The theoretical determinations of the form of the earth by Newton and Huygens were at variance with the results of geodetic operations that had been carried on in France under the superintendence of the first Cassini, from 1680 till 1716, for the purpose of making a geometrical survey of that country. Cassini found the degree of the meridian to the south of Paris to be 57,092 toises, while on the north of that city it was only 56,960 toises. This result led to the conclusion that the earth is a protracted spheroid, or elongated at the poles; a conclusion entirely inconsistent with the principles of hydrostatic equilibrium, and the deductions of Newton and Huygens. The question, however, was of too great importance to astronomy to be allowed to remain undecided. Accordingly, the Academy of Sciences of Paris determined to apply a decisive test, by the measurement of arcs at a great distance from each other. For this purpose some of the most distinguished members of their body undertook the measurement of two meridional arcs, one in the neighbourhood of the equator, and the other in a high latitude. In 1735 Godin, Bouguer, and La Condamine, proceeded to Peru, where they were joined by two Spanish officers, Don Georges Juan and Antonio d'Ulloa, and, after ten years of laborious exertion, they measured an arc of above three degrees, between the parallels of 2′ north and 3° 4′ 32″ south latitude. The other party, consisting of Maupertuis, Clairaut, Camus, Lemonnier, Outhier, and Celsius, were in some respects more fortunate, inasmuch as they completed the measurement of an arc near the polar circle, of 57 minutes, and returned to Europe within sixteen months from the period of their departure.

The measurement of Bouguer was executed with great care; and, on account of the locality (the extremities being on different sides of the equator), as well as the excellent manner in which all the details were conducted, it has always been regarded as a most valuable determination. The original base was measured twice, and the difference between the two measures was scarcely two and a half inches. A second base of 5259 toises was measured with the most scrupulous attention by Bouguer, Condamine, and Ulloa, near the southern extremity of the arc, and the result differed less than a toise from the length calculated from the triangles. The latitudes at the two extremities of the arc were determined by simultaneous observations of the same star with zenith sectors. In fact, as the nutation of the earth's axis was then unknown, and as a considerable time necessarily elapsed before a large instrument could be transported from one extremity of the arc to the other, the results of successive observations with a single instrument presented little accordance. By the simultaneous observations, the greatest deviation from the mean did not exceed three or four seconds.

In consequence of a misunderstanding that unhappily sprung up among the principal persons engaged in this memorable expedition, their operations were conducted separately, and we have accordingly three independent results, but all agreeing very nearly with each other. The first is that of Bouguer, who found, after the various reductions, the length of the degree of the meridian at the equator, and reduced to the level of the sea, to be 56,753 toises. Condamine found 56,749 toises, and the Spanish officers 56,768 toises.

The party of Maupertuis, though their labours were sooner completed, had also to contend with very great difficulties. At their departure from France they had hoped to find a sufficient number of stations among the small islands situated in the Gulf of Bothnia; but on their arrival it was found impracticable to carry on a triangulation among the islands, consequently they were obliged to penetrate into the forests of Lapland. They commenced their operations at Tornea, a city situated on the mainland near the extremity of the gulf, and which formed the southern extremity of their arc. From this place they carried a chain of triangles northward to the mountain of Kittis, lat. 65° 51′. Here they commenced the observations of latitude by observing the distance of their zenith from the star δ Draconis; and having obtained a sufficient number of observations, they returned to Tornea, to determine the latitude of their station there in the same manner. At Tornea they observed not only the star δ Draconis, but also α Draconis; and some doubt having arisen respecting the accuracy of the determination at Kittis, they again repaired to that station, to observe the last star there also. The amplitude of the celestial arc was found, by taking the mean of the observations, to be 57′ 29″·6.

It now remained only to measure a base, and thereby determine the terrestrial distance between Tornea and Kittis. This was accomplished on the frozen surface of the river, by two parties who measured separately, and the difference between their results amounted only to about four inches. From this it resulted that the terrestrial arc between Tornea and Kittis was 55,023 toises, giving 57,437 toises to the degree, and consequently exceeding the degree measured by Picard in France by 337 toises.

As all these determinations concurred in proving that the degrees of the meridian increase very sensibly in length from the equator to the high latitudes, no doubt could any longer be entertained that the earth is compressed at the poles. The operations of the two Cassinis in France alone gave results leading to an opposite conclusion; and it therefore became desirable to ascertain the cause of the anomaly. For this purpose Maupertuis and his former associates undertook the verification of Picard's operations; and it resulted from the remeasurement of the arc between Paris and Amiens that the degree was equal to 57,183 toises. But a more extensive series of operations was undertaken some time after by Cassini de Thury (the third of that name) and Lacaille. With a view to determine more accurately the variation of the degree along the French meridian, they divided the whole arc between Dunkirk and Collioure into four partial arcs, embracing about 2° each, by observing the latitudes at five different stations. While engaged in this measurement, they discovered that the toise which had been used by Picard was shorter by about a thousandth part of the whole than that which formed their standard, and that his final results were accordingly too great by about a thousandth part. They also found the mean length of a degree between Paris and Bourges to be 57,071 toises; between Bourges and Rhodez only 57,040 toises; and between Rhodez and Perpignan 57,048 toises; thus showing on the whole a very sensible diminution as we proceed towards the south. The last portion which they examined was that between Paris and Dunkirk; and after a very careful determination of the latitudes, and the measurement of a base of verification near Dunkirk, they found the degree to be 57,074 toises, greater than any of the former, as ought to be the case on the hypothesis of a polar compression.

Another important operation was likewise undertaken by Cassini and Lacaille, namely, the measurement of a degree of a parallel of latitude. The place they selected was near the mouths of the Rhone, under the forty-third parallel. One of the observers took his station on the mountain Sainte Victoire, near Aix, and the other on Saint Clair, near Cette. On the tower of the church of Sainte Marie, a village situated between the two stations, a signal was made by firing a quantity of loose gunpowder; and the instant of the flash was noted by each of the observers. The difference of sidereal time thus determined was 7 minutes 33·25 seconds, corresponding to a difference of meridians of 1° 53′ 19″. The distance between the two stations, which was ascertained by triangulation, being reduced to the distance on the parallel intercepted between the two meridians (at the latitude of 43°), was found to be 78,663 toises, whence the length of the degree was computed to be 41,651 toises. This exceeded by about 250 toises the length of a degree of the same parallel computed on the hypothesis of the earth's being a perfect sphere. The details of all these operations are given in the *Meridienne de Paris Vérifiée*.

About the middle of the last century several arcs of meridian were measured in various countries, which, though of inferior importance in comparison of the more extensive surveys which have since been undertaken, are nevertheless deserving of enumeration. In 1751 Lacaille measured an arc at the Cape of Good Hope, whither he had gone for the purpose of determining the lunar parallax, and making other astronomical observations. At the latitude of 38° 18½′ he found the degree of the meridian to be 57,037 toises. This result was nearly the same as had been obtained in France, 10° farther from the equator; and clearly proved either the existence of great local irregularities in the form of the earth, or the dissimilarity of the two terrestrial hemispheres. Considerable disposition has been manifested by later observers to question the accuracy of this result; fortunately the details of the operations have been preserved, and, on a careful investigation of them by Delambre, no error of any importance was found either in the methods or the calculations. If there is any considerable inaccuracy, it must have proceeded from the use of inadequate instruments. But, after making all reasonable allowance for this cause of error, the Cape degree still continues to appear anomalous; and it would be desirable to have the whole of Lacaille's arc re-measured.

In 1751 the measurement of a terrestrial arc was undertaken in the Roman states by the Jesuits Maire and Boscovich. It extended nearly two degrees, between Rome and Rimini, and it was found that the degree of meridian between these parallels, namely, 42° and 44°, contained 56,973 toises. The details are given at length by Boscovich, in a work of great elegance, and entitled *De Litteraria Expeditione per Pontificiam ditionem*, &c. Romæ, 1755.

Liesganig, a Jesuit, in 1762 also executed two measures of a meridional degree, one in Hungary and the other in the Austrian states; but it has been shown by Baron Zach, in his *Correspondence Astronomique*, vol. vii. that the results merit no confidence, and, in fact, would lead to certain error if employed as elements in determining the figure of the earth.

About the same time, in 1764, an arc of meridian was measured in North America, on the peninsula between the Chesapeake and Delaware bays, by two Englishmen, Charles Mason and Jeremiah Dixon. They employed no triangulation, but measured the line with deal rods along the whole extent of the arc, the mean latitude of which was 39° 12′. Their rods were afterwards compared with the five-feet brass rods made by Bird. The latitudes were determined with a zenith sector. The length of the degree, after the necessary corrections and reductions were made, was found to be 60,625 English fathoms, or 56,888 toises. There is no doubt that great care was bestowed on this operation; it is, however, easy to see that the measurement of so long a line by means of rods is liable to many causes of error from which the method of triangulation is exempt.

In 1777 Beccaria undertook to measure a degree in the plains of Piedmont. He found the degree of the meridian at the latitude of 44° 44′ to contain 57,024 toises; but great uncertainty remained respecting the correctness of the latitudes, the extreme points of the arc being in the near neighbourhood of immense ranges of mountains, which could not fail to produce a very considerable deviation of the plumb line. It was supposed that as both ends of the arc were terminated by mountain ranges, whereas Boscovich's arc had been carried across the Appennines and terminated at the sea coast, the errors of the two measures occasioned by the local attraction, being of opposite kinds, would neutralize each other, and give a correct mean result.

Amidst the rapid advances of mathematical science towards the end of last century, the determination of the figure of the earth was not overlooked. In the year 1785 a memorial was presented to the British government by Cassini de Thury, stating the important advantages that would result to astronomy and navigation, from having the difference of longitude of the Greenwich and Paris observatories determined by a geodetic measurement. Fortunately this proposal was agreed to. The English operations were placed under the superintendence of General Roy, who to active and indefatigable zeal united great skill and experience in practical astronomy and surveying. In the summer of 1784 a base of rather more than five miles was measured on Hounslow Heath. In the measurement of this base, deal rods were at first employed; but as these were found to warp, and be affected with the variations of the hygrometrical state of the atmosphere, glass tubes were substituted; and in 1791 the same base was measured with a steel chain carefully made by Ramsden, yet the difference from the former measure was found to be only three inches. The mean result was 27,404·2 feet reduced to the level of the sea, and the scale being taken at the temperature of 62° of Fahrenheit. A chain of 32 triangles, in connection with this base, extended over the country to Dover and Hastings; and two more, stretching across the channel, connected them with the French signals on the opposite side. The instruments employed in this survey were of the most excellent description, and far superior to any that had ever been employed in similar operations. The angles of each triangle were measured by a large theodolite constructed by Ramsden; and it was this splendid instrument that first exhibited the *spherical excess*, or the minute quantity by which, on account of the sphericity of the earth, the sum of the three angles of a triangle on the earth's surface exceeds 180°.

The French part of this great operation was conducted with equal ability by Cassini (the fourth of that name), Mechain, and Delambre. The angles were measured with the repeating circle of Borda; an instrument of a very different description from the theodolite, but which in geodetic operations may fairly be allowed to give, if not equally, at least sufficiently correct results, while in practice it is much more commodious. The result of the combined measures showed the meridian of Paris to be 2° 19′ 51″ east of Greenwich, or 9″ less than had been determined by Dr Maskelyne.

Soon after this time a series of geodetic measurements was commenced both in France and England, which, in point of extent, as well as minute accuracy, far surpassed all the operations which had yet been undertaken with a view to determine the figure of the earth. In 1791 the National Convention of France having agreed to remodel the system of weights and measures, determined to adopt a standard taken from nature, which might be universally applicable in all countries, and capable of being restored in any future age, if by accident it should happen to be lost. Two such standards were proposed,—namely, the length of the pendulum, which makes a given number of vibrations in a given latitude; and the quadrant of the terrestrial meridian. Of these the pendulum is by far the most easy to be determined; but it was objected, that as the length of the pendulum varies at different latitudes, and also depends in some degree on the geological character of the country where it is measured, its length, if it should happen to be lost, could not be recovered, without knowing the precise place at which it had formerly been determined. The length of the quadrant of the meridian is, however, invariable, and, if the earth is a regular spheroid of revolution, must be the same at all places. Accordingly, the Convention chose the ten millionth part of the meridian from the equator to the pole as the unit of their new scale; and in order that this unit might be determined with the greatest possible precision, it was resolved to remeasure the arc of the meridian of Paris, and to extend it from Dunkirk to Barcelona, a distance comprehending altogether an arc of about nine degrees. The practical execution of this undertaking was confided to two astronomers of distinguished ability, Delambre and Mechain, by whom the requisite operations were carried on during the years 1792, 1793, and 1794, amidst all the dangers and difficulties arising from the disorganized state of the country, with a resolution and courage of which the annals of science afford few examples. The triangles amounted to 115 in number. Each of the three angles of every triangle was separately observed with the repeating circle. The different observations, with the original registers and remarks of the observers, were compared by commissioners, among whom were some of the ablest men in France. A form was drawn up, after which all the calculations were made. The calculations of the triangles, as well as of the azimuths, were examined by Tralles, Van Swinden, Legendre, and Delambre himself. The triangles were connected in the neighbourhood of Paris with a base of upwards of seven miles in length, being 6075·9 toises, at the temperature of 16¼ centigrade, or 61¼ of Fahrenheit. A base of verification of 6006·25 toises was measured by Mechain, near Perpignan, at the southern extremity of the arc; and the measured length was found to differ by less than a foot from the length deduced by calculation from the first base, though the distance was more than 436 miles. A line of this length, measured with extreme precision, is obviously quite sufficient to enable us to infer, with all the requisite exactness, the length of the quadrantal arc; but the French astronomers resolved to extend the triangulation still farther. Accordingly, Mechain repaired again to Spain, and in the year 1805 continued the chain of triangles from Barcelona to Tortosa, on the coast of the Mediterranean. At this place his labours were prematurely terminated by an epidemic fever. The prolongation of the arc was, however, committed to two philosophers of distinguished reputation, Biot and Arago. An immense triangle, one of the sides of which exceeded 100 miles, connected the coast of Valentia with the small island of Formentera, the most southerly of the Balearic group, and distant no less than 12° 22′ 13″·39 from Dunkirk, the northern extremity of the arc. The result of the whole gave a value of the quadrantal arc, differing somewhat from that determined by Delambre and Mechain, but so little that the length of the toise would be scarcely affected by four times the millionth part of itself. The details of this magnificent operation are given at length in the four volumes of the *Base Metrique.*

The English survey, which had been interrupted by the death of General Roy in 1790, was resumed in 1793 under the direction of Colonel Mudge. The original triangles between Greenwich and Dover were extended along the coast to Dunnose in the Isle of Wight, and thence through Devonshire and Wiltshire, and connected with a base of verification measured on Salisbury Plain. The length of this base was found, after the proper reductions, to be 36574·4 feet, differing scarcely one inch from the length deduced by calculation from the base on Hounslow Heath. So near a coincidence, though probably owing in some degree to a compensation of errors, affords a convincing proof of the extreme accuracy with which every part of the operation had been conducted. In 1802 the triangulation was carried into Yorkshire, and a meridian arc measured from Dunnose to Clifton. The latitudes at the terminal points were determined with Ramsden's zenith sector. The arc was afterwards extended to Burleigh Moor, comprehending nearly four degrees. It may be remarked, that both the French and English arcs present this singular anomaly, that when portions of them, at particular places, are considered separately, the length of the degree appears to increase on going southward.

The survey has been continued, with occasional interruptions, up to the present time, under the able direction of Lieutenant-Colonel Colby; and the triangulation has been carried to the remotest parts of Scotland, and over a considerable part of Ireland. In the course of the operations, several important improvements, both in respect of the instruments employed, and in the method of conducting geodetic measurements in general, have been introduced into practice. A base of upwards of seven miles has been measured near Londonderry; and it now only remains to determine the latitudes of some stations, to give us the elements of a new and greatly prolonged arc.

In the years 1801, 1802, and 1803, Maupertuis' Swedish arc was re-measured by Svanberg, and extended nearly 40′ to the south. The methods were the same as had been employed by Delambre. The extremities of the new arc were at Mallörn and Pahtawara. The distance was found to be 92,778 toises, and the difference of the latitudes 1° 37′ 20″·3; whence 1° = 57,196 toises. This agrees much better than the result of Maupertuis (57,422 toises) with other measures; but the difference, which implies an error of 12″ in the latitude of Kittis as determined by the French academicians, has not been satisfactorily accounted for; so that there is still some doubt about the length of the degree in that latitude. (See Svanberg's *Exposition des Operations faites en Laponie,* &c. Stockholm, 1805.)

Since the beginning of the present century, two arcs of

Figure of the Earth.

f meridian have been surveyed in India. The first was in n the neighbourhood of Madras, and comprehended only 1° 35′. The second, however, is the longest which has yet been measured. The first, and a large part of the second, was accomplished under the direction of Colonel Lambton; and the instruments and methods of observation and calculation were exactly the same as those that had been employed by Colonel Mudge in the English survey. The southern extremity of the second arc was at Punnæ, near Cape Comorin, latitude 8° 9′ 32″·51; and the northern at Daumergidda, latitude 18° 3′ 16″·07. The amplitude is consequently 9° 53′ 43″·56, and the distance between the extremities was found to be 598,629·98 fathoms (about 680 miles), giving 60,495 fathoms, or 362,970 feet, for the length of the degree. Several bases were measured, and the whole of the operations appear to have been conducted with great skill and accuracy. This arc has since been extended by Captain Everest to Kulliampoor, latitude 24° 7′ 11″·8; so that the whole length now includes very nearly sixteen degrees. The details of Colonel Lambton's operations are given in the different volumes of the *Asiatic Researches* (see vols. viii. x. xii.), and those of Captain Everest, in his "*Account of the Measurement of an Arc of the Meridian between the Parallels of* 18° 3′ *and* 24° 7′," printed at the expense of the East India Company, but not yet published.

Various geodetic operations on a less extensive scale have been recently executed, which are better adapted, perhaps, to give information respecting the local curvature than the general form of the earth. Beccaria's arc has been remeasured by Plana and Carlini: the results clearly demonstrate the existence of some errors in the original measurement, but they are not yet altogether satisfactory, and the country is very unfavourable. The distance between Göttingen and Altona has been measured by Gauss; and the amplitude of the corresponding celestial arc is known with the utmost precision, from observations of the latitude made at the respective observatories of the two places. The amplitude, however, is only about two degrees, and there is some doubt about the exact length of the iron bars with which the base was measured. A more extensive arc has been measured in Russia by Struve. It extends at present to three and a half degrees, and it is understood that it is in contemplation to prolong it still farther. Many new methods have been employed in this measurement; and it acquires additional value from its high latitude, and the acknowledged skill and accuracy of the observer.

The above are the principal arcs of meridian, but some arcs of parallel have also been measured. Theoretically speaking, the figure of the earth may be determined from the measurement of arcs of parallel, as readily as from meridional arcs; and the geodetical operations in the one case differ in no respect from those in the other. But the great, and, we fear, insurmountable difficulty, is to determine with sufficient precision the difference of astronomical longitudes. In a subsequent part of this article we shall have again occasion to mention Cassini's measurement of an arc of parallel across the mouth of the Rhone; of the English arc between Beachy Head and Dunnose; and that recently made from Marennes to Padua.

The problem of determining the earth's figure from the laws of hydrostatic equilibrium has not yet received the complete solution which the present advanced state of analytical science might lead us to expect. We have already mentioned the results found by Newton and Huygens. Maclaurin first demonstrated that the ellipsoid f revolution is a figure which satisfies the conditions of quilibrium in the case of a revolving homogeneous body, whose particles attract one another according to the law of the inverse square of the distance; and he moreover determined the amount of the attraction in a particle situated anywhere on the surface of such a body. This was an important step towards the solution of the problem. A few years afterwards, Clairaut published his *Théorie de la Figure de la Terre*, which, among other results, demonstrated with uncommon elegance, contained a very remarkable theorem which establishes a relation between the oblateness of the earth and the variations of gravity at different points of its surface, and consequently gives the means of determining the earth's figure by means of observations of the length of the seconds pendulum at different latitudes. Maclaurin's discovery gave the intensity of the gravitating force on the surface of the spheroid, or in its interior; but it was necessary to assign the force with which an exterior point is attracted. This was partly accomplished by D'Alembert, who proved that the attraction of any ellipsoid whatever upon a point situated in the prolongation of one of its axes, is to the attraction of a similar spheroid having the same centre, and passing through the attracted point, as the mass of the first spheroid is to the mass of the second. Legendre found an approximate expression by means of series, for the attraction on a point placed anywhere without a spheroid of revolution; and Laplace extended the solution to ellipsoids in general. But the complete solution was reserved for Mr Ivory, who obtained in finite terms a very simple expression for the attractive force of an ellipsoid on an exterior point, and thereby completed the theory of Maclaurin. It may be stated in a general way, that notwithstanding all the researches that have been made respecting this very intricate subject, the only positive results which theory has yet supplied are the three following:—1*st*, Maclaurin's demonstration that a homogeneous mass revolving about an axis will be in equilibrio with the figure of an ellipsoid of revolution; 2*d*, Clairaut's theorem for determining the ellipticity by means of pendulum observations; and, 3*d*, the expression for the attraction of ellipsoids on exterior particles, found by Mr Ivory. A complete theory would determine whether there are or are not other figures besides the ellipsoid, under which the equilibrium could subsist; but this has not yet been accomplished. Indeed it has not even been proved that the sphere is the only figure which could be assumed by a body at perfect rest, and whose molecules are subjected to no other forces than their mutual attractions.

Our limits do not permit us to enter into details respecting the numerous experiments that have been made of late years to determine the figure of the earth by measuring the variations of gravity at different places by means of the pendulum. The most valuable series of observations of this kind we yet possess are those of Captain Foster, reduced under the direction of Mr Baily, and published in the *Memoirs of the Royal Astronomical Society*, vol. vii. But a discovery recently made by Bessel proves that less accuracy has been obtained by this method than was supposed. It has been found, that a pendulum, when vibrating, drags along with it a portion of air, the precise effect of which can be ascertained in no other way than by actual experiment in vacuo with each individual pendulum. The probable correction which it would be necessary to apply to the results that have already been found, cannot be satisfactorily determined.

The mean of the pendulum experiments gives rather a higher value of the ellipticity than the results of geodetic measures; but there are many elements, particularly the irregular constitution of the exterior crust of the earth, and the density of the strata surrounding the station, which can scarcely be determined, and which yet affect materially the results of the experiments. This subject will be resumed under the article Pendulum.

Besides the methods which have now been alluded to, physical astronomy furnishes other means of arriving at a knowledge of the figure of the earth. The precession of the equinoxes, and nutation of the earth's axis, are phenomena depending on the compression of the earth; and as their amount is now ascertained, from astronomical observations, with the utmost accuracy, we can reciprocally deduce from them a knowledge of the compression. They do not, however, give us an absolute value of the amount of compression, but they make known the limits within which it must necessarily be confined. These limits are $\frac{1}{279}$ and $\frac{1}{378}$. But a more delicate measure of the same element is furnished by some irregularities in the moon's motion to which it gives rise; and as the lunar theory has now attained a very high state of perfection, and as the small irregularities which cause so much perplexity in geodetical measures here entirely disappear, this is perhaps the most satisfactory method of all of determining the ellipticity of the earth. The equations into which the irregularity in question enters were discovered by Laplace; and the ellipticity necessary to produce the observed effect was found, on calculation, to be $\frac{1}{304}$; confirming in a most remarkable manner the deductions from the measurement of arcs and the observations of the pendulum.

SECTION II.

OF THE MEASUREMENT OF TERRESTRIAL ARCS.

The determination of the figure of the earth, being founded on the comparison of lines actually measured on its surface with the corresponding arcs of the celestial sphere, requires a combination of geodetical and astronomical operations, which it will be our object in the present section to explain. Theoretically considered, the geodetical line to be measured may lie in any direction, because it can always be reduced to the meridian or to any other given direction; but, for practical reasons, which will be pointed out hereafter, it ought to be taken, as nearly as the nature of the country in which the measurement is made will permit, either in the direction of the meridian, or of a parallel of latitude. Differences of latitude, however, can be determined with greater precision than differences of longitude; the meridional arcs are consequently the best adapted to the purpose. Satisfactory results can only be obtained from the measurement of lines of very considerable length, for example, of several degrees; and this circumstance renders the geodetical operations both laborious and complicated. In no place of the world, probably, and certainly in no populous country, could it be possible to find a territory so free from obstructions as to admit of the direct measurement of a line of two or three hundred miles in the same direction. Hence, when an operation of this nature is to be undertaken, the country in which the direction of the line to be measured lies is divided into triangles; the angles of each triangle are accurately observed with a theodolite, or some other equivalent instrument; and the side of one of them being actually measured, all the other sides are computed from it by the rules of trigonometry. In this manner the length of the whole line is ascertained, and on comparing it with the celestial arc, the data are obtained for deducing the dimensions and form of the earth.

It appears, then, that in order to determine the figure of the earth by the measurement of degrees, four distinct sets of operations are necessary: 1*st*, The measurement of one side of a triangle, or of *the base* as it is called; 2*d*, the observation of the angles of each triangle, together with the height of the station, in order that the triangles may be reduced, if necessary, to the horizontal plane, and to the level of the sea; 3*d*, the observation of the *azimuths* of the sides of the triangles, or the angles they make with the meridional line; 4*th*, the latitudes of the extreme points of the line. It is immaterial in what order these operations are undertaken. We shall begin with the measurement of the base.

The length of the base must be regulated in some degree by the nature of the locality; but being the fundamental element from which the sides of all the triangles are deduced, it should not be less than five or six miles. A piece of ground must therefore be selected, as nearly level as possible, and admitting a line of that length to be described on it. The direction of the base is first marked out by pickets; and, in order to place these in the same straight line, or rather in the same vertical plane, a telescope, mounted in the manner of a transit instrument, is set up at one extremity, by means of which the observer is enabled to direct an assistant, by signals, to the exact position in which the picket is to be placed, and also to bring their tops exactly into the same level. As a farther guide, a rope may then be stretched between the pickets; and, for greater security in the subsequent operations, the whole extent may be approximately measured by rods or chains, in the usual manner. The extremities of the base ought to be permanently marked by points. The centres of metal tubes, cannon for example, let into the ground to a considerable depth, answer this purpose very conveniently.

These preliminary operations being accomplished, the next step is to proceed to the more delicate operation of measuring the exact distance between the terminal points, or extremities of the base.

Various methods have been practised for this purpose. In the measurement of the first base of the trigonometrical survey on Hounslow Heath by General Roy, deal rods were at first employed, as had been done by Lacaille, Lemonnier, and others; but though every precaution was used in selecting the best seasoned timber, and every means employed to secure the rods from flexure, it was discovered, in the course of the operations, that they were liable, from variations in the state of the atmosphere as to moisture or dryness, to sudden and irregular changes of such magnitude as to destroy all confidence in the results. They were therefore laid aside; and glass rods, consisting of straight tubes twenty feet in length, and about an inch in diameter, and enclosed in wooden cases, were substituted. The only alteration to which these were subject arose from the expansion and contraction from variations of temperature; and as such alterations follow constant and ascertainable laws, their effects could be easily computed, and a correction made for them. But the apparatus ultimately adopted, both in the measurement of this base, and the other bases subsequently measured for the purpose of verifying the operations in the English survey, consisted of two steel chains, made with great care by Ramsden, of a hundred feet in length, and composed each of forty links, joined in the manner of a watch chain. The chains were supported by deal coffers, and after being placed in a straight line, were stretched with a weight of fifty-six pounds. Their temperature and inclination to the horizon were carefully noted at the same time, and the proper corrections subsequently made.

This method has been objected to, on account of the uncertainty of giving the chain always the same degree of tension, and of the rubbing and wear of the joints; but the best proof of the accuracy of the results obtained by it consists in the fact, that the two measurements of the base on Hounslow Heath, first by glass rods, and secondly by the steel chains, differed from each other, after all the reductions were made, by less than three inches, although the whole length exceeded five miles. For an account of the comparison of the chains with one another, and with the standard brass yard made by Ramsden, we must refer to the *Philosophical Transactions*, vol. i.

The use of chains has been confined to the English and Indian surveys. Bouguer, in the Peruvian measurement, employed an iron rod of about a toise in length, which, from the frequent comparisons that have since been made of it with other standards, has been particularised by the name of toise of Peru. For the determination of the meridian of Dunkirk, Borda employed rules of platina, exactly two toises in length, and furnished with a very ingenious contrivance for ascertaining the expansion. Along one side of the rule there was a slip of brass, firmly fixed at one extremity, but at liberty to move along the rule at the other end, according to the relative expansion of the two metals. The relative expansion being read off by means of a micrometer, gave a ready means of computing, from tables previously constructed, the absolute expansion of the platina rule. Four rules were made use of, three of which were always placed on the ground at once; and in order to prevent any derangement, they were not brought into absolute contact. A small interval of a few millimetres was left between them, which was measured by means of a slider attached to the preceding end of each rule, and which was pushed out till it came into contact with the following end of the preceding rule. See Delambre, *Astronomie*, tome iii. p. 538, or *Base du Systême Metrique*.

Various other contrivances have been used for the measurement of the base line. MM. Plana and Carlini, in the re-measurement of Beccaria's arc, employed measuring rods of wood, twelve metres in length, of the form of hollow parallelepipeds. For the Hanoverian base measure, between Altona and Gottingen, Gauss employed three rods of hammered iron, each twelve French feet in length. But the most ingenious apparatus which has yet been invented for this purpose, is that which was made by our celebrated artist Troughton for the Irish base. As this instrument is probably destined to supersede all others previously used, we shall briefly describe the principle on which it is constructed.

Let AB and DE (Plate CCXLIV. fig. 1) represent two bars of different metals, firmly united to a transverse bar at the middle C, but entirely free to move independently of each other at the extremities, according to their different expansions. AP and BQ are two tongues of steel attached to the extremities of the two rods AD and BE, by double conical joints, around which they are capable of making a small angle with the lines perpendicular to AB or DE. At a certain given temperature the bars are exactly of the same length, when, consequently, AP and BQ are parallel to each other, and perpendicular to the bars. Let us now conceive the bars to receive an increase of temperature, and that the dilatation of AB is greater than that of DE. In consequence of the increased temperature, both bars will be lengthened, but their lengths will no longer be equal; consequently the two tongues AP and BQ will no longer be parallel; for, suppose AB to become *ab*, and DE to become *de*, then AB being by hypothesis a more expansive metal than DE, *ab* will be longer than *de*, and the steel tongues will take the positions *ax* and *by*, inclined to each other. But if the point P is taken at such a distance from the bars that PA is to PD in the ratio of the dilatation of AB to DE, then in the new position *ax*, the point P will not sensibly deviate from the perpendicular AP, at least for moderate variations of temperature. In the same manner, the point Q will not sensibly deviate from its first position in the perpendicular BQ, so that the distance between P and Q remains sensibly the same. It is easy, however, to see that the dilatation of the bars must be confined within narrow limits; for, as the length of the tongue is invariable, P will not be found exactly in the line AP after the expansion has taken place; it will be on the same side of AP on which are the points *a* and *d*, and its distance from AP will be accurately measured by the quantity AP × (tan. APa — sin. APa); and as the same thing takes place with regard to Q, the distance between P and Q will be increased by twice this quantity. But as the angle APa must in all cases be extremely small, the difference between its tangent and its sine is altogether inappreciable. It is unnecessary to remark, that the same consequences (*mutatis mutandis*) take place when the temperature falls below the assumed standard.

In the instruments made use of in the measurement of the Irish base, the bar AB was of brass, and DE of iron. The length of each was ten feet, and the distance between them two inches. The length of the tongue is hence easily found from the relative dilatation of the two metals. Suppose the expansion of brass to be to that of iron in the ratio of 83 to 53 for an increase of 1° of temperature, and let PD $= x$ inches, we shall have $x : x + 2 = 53 : 83$; whence $x = \frac{53}{15} = 3\frac{1}{2}$ inches very nearly. But the precise position of the points P and Q must be determined by actual experiment: for the expansion or contraction of no two bars, even of the same metal, are ever found to be exactly the same.

In practice, five or six sets of bars, constructed in the manner now described, and placed in strong deal boxes supported on trestles, are laid along the line to be measured, and accurately levelled. They are placed at a small distance from each other, and the distance between the dots on the adjacent steel tongues of two succeeding bars is accurately measured by an ingenious micrometrical apparatus constructed so as to form a compensating instrument of exactly the same nature as the measuring bars.

The conception of this elegant apparatus belongs to Lieutenant-Colonel Colby; and the practical results it gives correspond with its theoretical excellence. It is computed that the greatest possible error of the base measured on the eastern shore of Lough Foyle, in the county of Londonderry, cannot exceed two inches, though the length is very nearly eight miles.

The reduction to the level of the sea is made as follows: Let $r =$ radius of earth, $x =$ height above the level of the sea, $a =$ measured length of the base, and $a' =$ its reduced length; then

$$a' = a\left(\frac{r}{r+x}\right) = a\left(\frac{1}{1+\frac{x}{r}}\right) = a\left\{1 - \frac{x}{r} + \left(\frac{x}{r}\right)^2 -, \&c.\right\}$$

a series of which all the terms after the second may be neglected, by reason of their smallness.

It is easy to see, that as the base is not, correctly speaking, a straight line, but an arc of a circle, or rather ellipse, the sum of the lengths of all the rods or chains horizontally applied to it is not precisely the length of the arc, but of the circumscribing polygon. In order to determine how far this circumstance can affect the result, let us suppose the length of the measuring rod to be ten feet; when laid on the ground, exactly in the horizontal plane, it forms two tangents to the surface, of five feet each, and therefore each half length of the rod ought to be diminished by the difference between the tangent whose length is five feet, and the arc to which it belongs. Let A be the arc, then (ALGEBRA, Sect. XXV. H. 2)

$$\frac{\text{A}}{r}=\frac{\text{tan. A}}{r}-\tfrac{1}{3}\,\frac{\text{tan. A}^3}{r^3}+\&\text{c.}$$

whence $\text{tan. A}-\text{A}=\tfrac{1}{3}\,\frac{\text{tan. A}^3}{r^2}=\frac{125}{3r^2}$.

This must be multiplied by the number of times that the half rod, or five feet, is contained in the whole base. Supposing the base to be five miles, or 5280 times the length of the half rod, and the radius of the earth to be 4000 miles, or 4000 × 5280 feet, we should have tan. A — A $=\frac{125}{3\times 4000^2\times 5280}$ feet; a quantity which is altogether insensible.

We come now to the triangulation. The first thing to be done is to select proper stations for the vertices of the triangles. The selection will necessarily depend on the nature of the country through which the survey is made; but there are certain principles which ought to be observed, as nearly as the circumstances will permit. The stations should be chosen, so that each angle of the principal triangles should approach as nearly as possible to 60°, because a small error in the estimation of a very acute or obtuse angle will greatly affect the length of the opposite side computed from it. Excepting in unavoidable cases, no angle ought to be less than 30°. The sides cannot be too long, while the signal at one extremity is visible from the other. The signals may be towers, spires, or other conspicuous objects conveniently situated; but such signals can seldom be well bisected by the wire of the telescope. Flag-staffs are better when the distances are not too great. Delambre preferred signals erected on purpose. They were generally constructed of wood, and of the form of a truncated pyramid. One considerable advantage arises from the use of signals constructed in this manner, namely, that the instrument can be placed exactly at the centre of the station. Frequently Bengal lights, reverberating lamps, and white lights, are employed; but these of course can only be seen during the night. The best signal of this sort was invented by Lieutenant Drummond. It is formed by directing a stream of hydrogen gas on a small piece of ignited quicklime; an intense light is produced, which may be seen at very great distances. Care should be taken to place the signals, if they are to be observed by day, in such positions that they may be projected on the sky; if projected on forests or mountains, they will seldom be distinctly visible. Svanberg constructed his signals with openings, to permit the light of the sky to be seen through them.

The triangles being marked out, and the signals prepared, the next object is to measure the angles. When the theodolite is used for this purpose, no correction is required on account of the different altitudes of the signals, the reduction being effected by the instrument itself; but when a sextant or repeating circle is employed, the observed angles must be reduced to the plane of the horizon.

Let P, Q, and R (fig. 2), be the three stations, PQR the observed angle oblique to the horizon; produce PQ and PR till they meet Q′R′, a line parallel to the plane of the horizon; through Q′R′ let a plane be conceived to pass parallel to the horizontal plane, meeting PZ, the vertical passing through P, in P′; then Q′P′R′ is the horizontal projection of QPR, and the angles ZPQ, ZPR are the complements of the inclinations of the line PQ and PR to the horizon.

With P as a centre, and a radius = 1, let a sphere be described, intersecting PZ, PQ, and PR in the points A, B, and C respectively; the angle BAC is evidently equal to the horizontal angle Q′P′R′. Now, in the spherical triangle ABC, we have given by observation the side AB = the zenith distance of Q, AC = the zenith distance of R, and BC the oblique angle at the centre of the station, from which we are to find the angle BAC = Q′P′R′.

Let BC $=a$, AC $=b$, AB $=c$, and BAC = A. By a well-known formula of spherical trigonometry,

$$\text{cos. A}=\frac{\text{cos.}\,a-\text{cos.}\,b\,\text{cos.}\,c}{\text{sin.}\,b\ \text{sin.}\,c};\ \text{but cos. A}=1-2\ \text{sin.}^2\,\tfrac{1}{2}\,\text{A},$$

$$\text{therefore } 2\ \text{sin.}^2\,\tfrac{1}{2}\text{A}=1-\frac{\text{cos.}\,a-\text{cos.}\,b\ \text{cos.}\,c}{\text{sin.}\,b\ \text{sin.}\,c},$$

$$\text{and } 2\ \text{sin.}^2\,\tfrac{1}{2}\text{A}=\frac{\text{cos.}\,(b-c)-\text{cos.}\,a}{\text{sin.}\,b\ \text{sin.}\,c}.$$

Now, if p and q denote two arcs, we have (Algebra, XXV. D),

$$\text{cos.}\,p-\text{cos.}\,q=-2\ \text{sin.}\,\tfrac{1}{2}\,(p+q)\ \text{sin.}\,\tfrac{1}{2}\,(p-q),$$

therefore

$$\begin{aligned}\text{cos.}(b-c)-\text{cos.}\,a&=-2\ \text{sin.}\,\tfrac{1}{2}\,(a+b-c)\ \text{sin.}\,\tfrac{1}{2}(b-c-a)\\&=2\ \text{sin.}\,\tfrac{1}{2}\,(a+b-c)\ \text{sin.}\,\tfrac{1}{2}\,(a-b+c),\end{aligned}$$

and the equation becomes

$$\text{sin.}^2\,\tfrac{1}{2}\ \text{A}=\text{sin.}\ \frac{\tfrac{1}{2}(a+b-c)\ \text{sin.}\,\tfrac{1}{2}(a-b+c)}{\text{sin.}\,b\ \text{sin.}\,c}.$$

Let $\tfrac{1}{2}(a+b+c)=s$; then $\tfrac{1}{2}(a+b-c)=s-c$, and $\tfrac{1}{2}(a-b+c)=s-b$; consequently

$$\text{sin.}\,\tfrac{1}{2}\text{A}=\left(\frac{\text{sin.}\,(s-c)\ \text{sin.}\,(s-b)}{\text{sin.}\,b\ \text{sin.}\,c}\right)^{\frac{1}{2}}.$$

From this formula the value ot A is easily computed, when the inclinations of the lines PQ and PR to the horizon are not very small. In practice, however, it frequently happens that these inclinations are very small, or that the angles b and c differ very little from right angles. When this is the case, the logarithmic calculation of the formula becomes troublesome, particularly if it is required to determine A with great exactness; and it is better to adopt a different method of proceeding.

Instead of seeking to find the projected angle Q′P′R′, we may find its difference from the observed angle QPR, which difference will seldom amount to more than a few seconds. Since the arcs b and c are supposed to differ little from 90°, if we make $b=90°-\beta$, $c=90°-\gamma$, the angles β and γ will be very small. Substituting these values of b and c in the formula

$$\text{cos. A}=\frac{\text{cos.}\,a-\text{cos.}\,b\ \text{cos.}\,c}{\text{sin.}\,b\ \text{sin.}\,c}$$

it becomes

$$\text{cos. A}=\frac{\text{cos.}\,a-\text{sin.}\,\beta\ \text{sin.}\,\gamma}{\text{cos.}\,\beta\ \text{cos.}\,\gamma};$$

but

$$\text{sin.}\,\beta=\beta-\frac{\beta^3}{6}+\&\text{c., sin.}\,\gamma=\gamma-\frac{\gamma^3}{6}+,\ \&\text{c.}$$

$$\text{cos.}\,\beta=1-\frac{\beta^2}{2}+\&\text{c., cos.}\,\gamma=1-\frac{\gamma^2}{2}+,\ \&\text{c.};$$

therefore, on substituting, and rejecting all terms above those of the second order, we have

$$\text{cos. A}=\frac{\text{cos.}\,a-\beta\gamma}{1-\tfrac{1}{2}(\beta^2+\gamma^2)}=\text{cos.}\,a-\beta\gamma+\tfrac{1}{2}(\beta^2+\gamma^2)\ \text{cos.}\,a.$$

Let $\text{A}=a+x$. It is evident that when β and γ both vanish, x also vanishes, and we get $\text{A}=a$. Hence if β and γ be both very small, x is also very small, and consequently we may suppose its cosine $=1$, and its sine $=x$. In this case $\text{cos. A}\left\{=\text{cos.}\,(a+x)\right\}=\text{cos.}\,a\ \text{cos.}\,x-\text{sin.}\,a\ \text{sin.}\,x$ becomes

$$\text{cos. A}=\text{cos.}\,a-x\ \text{sin.}\,a.$$

Equating this with the former value of cos. A, we get

$$x\ \text{sin.}\,a=\beta\gamma-\tfrac{1}{2}(\beta^2+\gamma^2)\ \text{cos.}\,a,$$

whence

$$x=\frac{\beta\gamma-\frac{1}{2}(\beta^2+\gamma^2)\cos. a}{\sin. a}.$$

In order to adapt this fraction to logarithmic computation, let both its numerator and denominator be multiplied by 2; then, because $\cos. a=\cos.^2\frac{1}{2}a-\sin.^2\frac{1}{2}a$, and $2\beta\gamma=2\beta\gamma\cos.^2\frac{1}{2}a+2\beta\gamma\sin.^2\frac{1}{2}a$, we find, on multiplying and reducing,

$$2\beta\gamma-(\beta^2+\gamma^2)\cos. a=(\beta+\gamma)^2\sin.^2\tfrac{1}{2}a-(\beta-\gamma)^2\cos.^2\tfrac{1}{2}a;$$

but $\sin. a=2\sin.\frac{1}{2}a\cos.\frac{1}{2}a$; therefore, by substitution,

$$x=\left(\frac{\beta+\gamma}{2}\right)^2\tan.\tfrac{1}{2}a-\left(\frac{\beta-\gamma}{2}\right)^2\cot.\tfrac{1}{2}a.$$

Here the arcs x, β, γ are expressed in parts of the radius; but they are given by observation in minutes and seconds. Now an arc of 1″ may be considered as equal to its sine: hence the arc in seconds is to the arc in parts of the radius as 1″ to sin. 1″; consequently the arc in feet is equal to the arc in seconds × sin. 1″. Multiplying, therefore, by sin. 1″, we get

$$x=\left\{\left(\frac{\beta+\gamma}{2}\right)^2\tan.\tfrac{1}{2}a-\left(\frac{\beta-\gamma}{2}\right)^2\cot.\tfrac{1}{2}a\right\}\sin. 1''.$$

Another reduction is necessary. Unless the signals are constructed on purpose, it will rarely happen that the instrument can be placed exactly in the centre of the station. In this case it must be placed at some other point near the centre of the station, and the observed angle reduced to the centre by calculation. Suppose, for example, it were required to determine the angle ACB (fig. 3), which the objects A and B subtend at C, and that the instrument cannot be placed exactly at C. Let P be the point, at a short distance from C, where the instrument is actually placed, and APB be the observed angle; then, since CP can be measured, and CA, CB are supposed to be known, approximately at least, the problem is, having given the angle APB, and the distances CA, CB, and CP, it is required to determine the angle ACB.

Let AC and BP intersect in E. Then, since AEB= ACB+CBP=APB+CAP, we have

$$\text{ACB}-\text{APB}=\text{CAP}-\text{CBP}.$$

But $\sin.\text{CAP}=\frac{\text{CP}}{\text{CA}}\sin.\text{CPA}$, and likewise $\sin.\text{CBP}=\frac{\text{CP}}{\text{CB}}\sin.\text{CPB}$; therefore, making AC=$m$, BC=$n$, CP=$d$, ACB=C, APB=P, CPB=$p$, then CPA=P+$p$, and by substitution,

$$\sin.\text{CAP}=\frac{d}{m}\sin.(\text{P}+p),\text{ and }\sin.\text{CBP}=\frac{d}{n}\sin. p,\text{ whence,}$$

dividing by sin. 1″ to reduce the expression to seconds,

$$\text{CAP}=\frac{d}{m}\,\frac{\sin.(\text{P}+p)}{\sin. 1''},\text{ and CBP}=\frac{d}{n}\,\frac{\sin. p}{\sin. 1''};$$

therefore (since CAP − CBP = ACB − APB = C − P),

$$\text{C}-\text{P}=\frac{d\sin.(\text{P}+p)}{m\sin. 1''}-\frac{d\sin. p}{n\sin. 1''},$$

which gives C, or the angle ACB, expressed in seconds of a degree.

This expression is exact; but an approximation more convenient for calculation, and sufficient in almost every case that can occur in practice, was generally followed by Delambre. Let a circle be described about the triangle ABC, intersecting BP in D, and let CD, DA, and AB be joined. We have then ACB − APB=ADB − APB=DAP. Let the angle CDB (=CAB, which is known by observation) be denoted by A. In the triangle DPA,

$$\sin.\text{DAP}=\frac{\text{DP}}{\text{AD}}\sin.\text{APB}=\frac{\text{DP}}{\text{AD}}\sin.\text{P},$$

and in the triangle DPC,

$$\text{DP}=\text{PC}\frac{\sin.\text{PCD}}{\sin.\text{CDB}}=\text{PC}\frac{\sin.(\text{CDB}-\text{CPB})}{\sin.\text{CDB}},$$

$$\text{or DP}=d\,\frac{\sin.(\text{A}-p)}{\sin.\text{A}};\text{ therefore}$$

$$\sin.\text{DAP}=\frac{d}{\text{AD}}\,\frac{\sin.(\text{A}-p)}{\sin.\text{A}}\sin.\text{P}.$$

But AD may be considered as equal to AC=m; whence $\sin.\text{DAP}=\frac{d\sin.(\text{A}-p)\sin.\text{P}}{m\sin.\text{A}}$, and consequently, when expressed in seconds,

$$\text{DAP}=\text{C}-\text{P}=\frac{d\sin.(\text{A}-p)\sin.\text{P}}{m\sin.\text{A}\sin. 1''}.$$

This expression vanishes when A − p=0, or when the points P and D coincide, that is, when the instrument is placed on the circumference of the circle, circumscribing the triangle ACB. And it may be so placed, unless obstacles intervene, by moving it along the line PB, till the angle CDB is observed to be equal to BAC.

When the three observed angles of each triangle have been reduced to the horizon, they represent the angles of a spherical triangle, the sides of which are intercepted by the verticals of the three stations, and the sum of the three angles of each triangle exceeds 180° by a quantity which is called the *spherical excess*. The sides ought therefore to be calculated by the rules of spherical trigonometry; but as the sides of the triangles are in all cases very small in comparison of the radius of the earth, the calculation made in this way (for which indeed the existing tables are not well adapted) becomes exceedingly tedious. Instead, therefore, of calculating directly the spherical triangle, it is more convenient to compute its deviation, which is always very small, from a plane triangle. The method employed by Delambre was the following.

In the first place, the spherical angle, or that which is formed by tangents at the surface, must be reduced to the corresponding plane angle formed by the chords. This is easily accomplished by the help of the theorem above given for reducing the observed angles to the horizon; for the angle formed by the chord and the tangent of an arc is equal to the angle at the centre subtended by half the arc; consequently when the lengths of the two sides of a spherical angle are known nearly, the angle of *depression* of the chords is also known; and therefore the preceding theorem for reducing angles to the horizon can be immediately applied. For example, suppose the sides of a spherical angle to be respectively p and q miles, and the circumference of the earth to be 25,000 miles, then

$$25{,}000 : p :: 360^\circ : \frac{360^\circ\,p}{25{,}000},\text{ or }\frac{21{,}600''p}{25{,}000}=\frac{108\,p}{125}\text{ seconds}$$

of a degree, which is the angle subtended at the centre by the whole arc; and consequently one half of it, or $\frac{54''p}{125}$, is the depression of the chord. In the same manner, $\frac{54''q}{125}$ is the depression of the chord of q; and by substituting these in the formula

$$x=\left\{\left(\frac{\beta+\gamma}{2}\right)^2\tan.\tfrac{1}{2}a-\left(\frac{\beta-\gamma}{2}\right)^2\cot.\tfrac{1}{2}a\right\}\sin. 1'',$$

we obtain the angles made by the chords, by means of which the triangle may be computed in the same manner as if it were a plane triangle.

To make this reduction, it is necessary to know, approximately at least, the diameter of the earth as well as the distances of the stations; but the result will be little affected by a moderate error in either of these data. In fact, it is only when the sides of the triangles are very large that the effects of the earth's curvature become at all sensible.

But a more elegant manner of estimating the effects of the earth's curvature, though not always of so easy application, was proposed by Legendre. This illustrious geometer discovered the following very remarkable property of spherical triangles; namely, that when the sides are very small in comparison of the radius of the sphere, if from each of the angles there be subtracted one third part of the quantity by which the sum of the three angles exceeds two right angles, or 180°, the angles thus diminished may be regarded as the angles of a plane triangle, the sides of which are equal in length to those of the proposed spherical triangle. The excess of the sum of the three angles above two right angles is proved by trigonometry to be equal to $\frac{a}{r^2}$, a being the area of the triangle, and r the radius of the sphere; so that the theorem of Legendre may be enumerated as follows:

"If the angles of a spherical triangle whose surface is small in comparison of the surface of the whole sphere, be denoted by A, B, and C, and the opposites by a, b, and c, the triangle may be calculated as a plane triangle, the sides of which are a, b, and c, and the opposite angles $A - \frac{1}{3}\varepsilon$, $B - \frac{1}{2}\varepsilon$, $C - \frac{1}{3}\varepsilon$, ε being the excess of the sum of the three angles of the proposed spherical triangle above two right angles."

In applying the above theorem, it is necessary first to calculate ε or $\frac{a}{r^2}$, which can always be done *a priori* from the known parts of the spherical triangle considered as rectilinear. This being done, we have only to deduct $\frac{1}{3}\varepsilon$ from each of the observed angles, and then compute the remaining parts, as in the case of a plane triangle.

By this method, the distances between the several signals may be computed; and as the angles at all the stations are given by observation, the inclinations of all the sides of the triangles to any one of them are also known, so that it is only necessary to determine very accurately the inclination of one side of a triangle to the meridian, in order to ascertain the inclinations of all the other sides, and thence to compute the meridian itself.

The determination of the azimuth of a signal is accomplished by means of astronomical observation, and may be performed in various ways, but all depending on the same principle. It is necessary, however, in any case to be provided with the means of determining the time with very great precision. The azimuth of the sun, or a star, at any given instant, can be determined with sufficient accuracy. Let the observer, therefore, take his station at one of the signals, and observe the angle formed between the other signal and the sun, or a star, when nearly in the horizon, and let him note the instant of time at which the observation was made. Knowing the error of his clock or chronometer, he knows also the true time, and can consequently calculate the azimuth of the observed celestial body. Taking the sum or difference, as the case may be, of this and the observed angle, he obtains the azimuth of the distant signal, or the angle which the straight line joining the two signals makes with the meridian. The refraction will scarcely effect the result; but a small error with respect to the time would lead to considerable errors. If the sun is observed, the error of the clock must be determined by observations of his meridional transits; but most frequently a circumpolar star, as Capella, is preferred. Sometimes the observation is made on the pole star itself; but in this case it is necessary to know the latitude of the station very accurately. Another method is frequently resorted to. Having set up a mark very nearly in the meridian, adjust a transit instrument upon it, and then, by means of the transits of stars at different polar distances, or other means known in practical astronomy, determine the deviation of the instrument from the meridian. This gives the direction of the mark with respect to the meridian, and consequently the angle to be added to or subtracted from the angle between the mark and the signal. For greater security, the azimuths may be observed at several signals. They ought at least to be observed at each extremity of the chain of triangles.

The triangles being calculated and reduced to the horizon, we are now in a condition to compute the length of the arc between the parallels of the extreme stations. Let ABCDEFG, &c. (fig. 4), be a chain of triangles lying nearly in the direction of the meridian AZ, and traced on a spheroidal surface, supposed to be formed by the continuation of the ocean. Let L be the last station, and LX the perpendicular passing through L and meeting AZ in the point X; it is required to determine AX.

By means of the previous calculations, all the sides of the triangles are supposed to have been computed, as well as the azimuth of C, or the inclination of AC to the meridian. Let CD be produced to M. In the triangle ACM there are given the side AC, and the two angles CAM, ACM. To find the third angle AMC, first compute the spherical excess ε; from each of the angles CAM, ACM, subtract $\frac{1}{3}\varepsilon$; take the sum of the two remainders from 180°, and there will be left the value of AMC. The angles being thus given, and also the side AC, the other two sides AM and CM are computed in the same manner as if the triangle were rectilinear.

In the quadrilateral MDFN there are given the two opposite angles at M and F (the first from the previous calculation, and the second by observation), together with the two sides MD and DF. Draw the diagonal MF; then in the triangle DMF there are given the two sides DM, DF, and the included angle D. From D deduct $\frac{1}{3}\varepsilon$, the excess ε being computed by an approximate value of the area of the triangle, and compute, as in a plane triangle, the side MF and the two angles DMF, DFM. To each of these add $\frac{1}{3}\varepsilon$, and the two sums being deducted from the angles DMN and DFN, there will remain the two angles FMN and MFN. Hence, since MF has been already computed, we can find MN, FN, and the angle MNF, in the usual manner.

Now, in the triangle NPH, NH is known (for FH and FN have been calculated), and the adjacent angles PNH, NHP are given by observation; therefore we can compute NP, PH, and the remaining angle NPH.

To find PX we may produce IL to Z, and resolve the two triangles PIZ and ZLX. In the first of these, the side PI, and the two adjacent angles PIZ, IPZ, are already known; whence we find IZ, PZ, and the angle IZP. We have then in the right-angled triangle LXZ, the side LZ, and the angle LZX to find ZX. From PZ subtract ZX, and there remains PX, the quantity sought.

In proceeding by the method now indicated, the spherical excess ε must be first computed for each of the triangles to be resolved; then each observed spherical angle must be diminished by $\frac{1}{3}\varepsilon$, in order to allow the calculations to be made by the rules of plane trigonometry; and when the result has been found, we must again add to each angle the small quantity $\frac{1}{3}\varepsilon$, in order to have the true spherical angle. (See Delambre, *Methodes Analytiques pour la Determination d'un Arc du Meridien.*)

It is necessary to remark, that the point X, determined by drawing a perpendicular from the last station to the meridian, is not situated exactly on the same parallel of latitude with L. Its latitude is a little greater than that of L; and unless the distance of the station from the meridian is very small, the difference will be sensible, and requires to be calculated. Conceive another point, L′ (fig. 5), on the same parallel of latitude with L, and at the same distance from the meridian on the opposite side. The point X is on the circumference of a great circle, perpendicular to the meridian PE, and passing through L and L′; but the small circle, or parallel of latitude of L and L′, intersects the meridian in a different point *l*. Now let PE (fig. 6) be the meridian, XC the intersection of its plane with that of the great circle passing through the points LL′, and *ln* the intersection of the plane of the meridian and the plane of the small circle or parallel of latitude passing through the same points LL′, so that E*l* is the latitude of L, EX that of the point X, and *l*X the distance between the perpendicular and the small circle passing through L. Let *ln* and XC intersect in *m*, then *l*X being a small arc, may be regarded as a straight line; consequently X*l* = *m*X tan. X*ml*. But X*ml* = XCE = latitude of L very nearly, consequently, taking λ to denote the latitude of L, we have X*l* = *m*X tan. λ. Now *m*X is the versed sine of the arc whose chord is LX; therefore, making $d =$ earth's diameter, $mX = \frac{LX^2}{d}$, and consequently $Xl = \frac{LX^2}{d} \tan.\ \lambda$, which is the quantity to be subtracted from the calculated meridional arc.

Delambre employed a different method of computing the distance between the parallels of the terminal points of the measured arc. It requires, however, the dimensions of the earth to be previously known with tolerable accuracy. Let AB (fig. 7) be the arc measured on the surface of the spheroid PAB; then, having observed the latitude of the station A, and the azimuth of AB, that is the angle BAP, we have sufficient data, supposing the dimensions of the earth to be nearly known, to find not only the distance between the parallels of A and B, but also the latitude and longitude of B, and the azimuth of BA, as observed from B. Through A and B draw the normals AM and BN, meeting the axis in M and N; join BM, AN; and about M as a centre, with an arbitrary radius, describe the circular arcs *bp*, *pa*, *ab*, forming the spherical triangle *pab*. Now, if we compare the triangle PAB on the spheroid with *pab* on the sphere, we find *pa* = PA in degrees, each being the colatitude of A; *pb* = PB, each being the colatitude of B; the angle *apb* = APB being the difference of longitude of A and B, and also the angle *pab* = PAB, each measuring the inclination of the planes PMA, AMB. But the angle *pba* is in general not equal to PBA; for as the normals do not meet the axis in the same point, the planes AMB and ANB do not coincide; and *pba* is the measure of the inclination of PMB and AMB, whereas PBA is the measure of the inclination of PMB and ANB. Now, in the triangle *pba* there are given the angles at *p* and *a*, so that if the side *ab* can be determined in terms of AB, the other parts of the triangle may be computed, and thence the difference between *pb* and *pa*, or the distance between the parallels, which being found in terms of BA, will be expressed in feet.

We have therefore to find an expression for *ab*, or the angle AMB. Now, in the triangle ABM there are given AB (the measured arc), and AM the normal at A (the dimensions of the earth being nearly known). But $BM = BN \frac{\sin.\ MNB}{\sin.\ NMB}$; and if we make $l =$ PNB the colatitude of B, and $x =$ NBM, we shall have $NMB = PNB - x = 90° - l - x$; therefore $\sin.\ NMB = \cos.\ (l + x)$; we have also $\sin.\ MNB = \sin.\ (90° - l) = \cos.\ l$; wherefore

$$BM = BN \frac{\cos.\ l}{\cos.\ (l + x)} =$$

$$BN \frac{\cos.\ l}{\cos.\ l \cos.\ x - \sin.\ l \sin.\ x} = BN \frac{1}{\cos.\ x - \tan.\ l \sin.\ x}$$

$$= BN\ (1 + \tan.\ l \sin.\ x + 2 \sin.^2 \frac{x}{2} +, \&c.$$

Now *x* is a very small angle; its sine is in fact expressed in terms of the square of the eccentricity, so that terms multiplied by it may be neglected without any sensible error. We may therefore assume BM = BN. In the triangle ABM we have then given the three sides, whence the angles may be computed, and consequently *ab* = AMB becomes known.

Having found *ab*, we have given in the triangle *abp* the two sides *pa*, *ab*, and the observed angle *pab*, from which to compute the remaining parts of the triangle, viz. *pb* the latitude of B, *apb* its longitude, and *pba* the azimuth of A, as seen from B. Make *pa′* = *pa*, and P*b′* to PB, then *ba′* = *pb* — *pa* is the distance between the parallels, the radius being unit; therefore, since 1 : MA : : *a′b* : A*b′*, we have A*b′* = AM × *a′b*, that is, the distance between the parallels of the extreme stations on the spheroid.

When the distance between the parallels of the extreme points of the arc has been ascertained, it only remains to determine the difference of their latitudes, or the length of the corresponding celestial arc. This is the most difficult part of the whole operation. The error of a single second in the difference of the latitudes corresponds to about a hundred feet on the terrestrial meridian; and when it is considered that the latitudes of the best determined spots on the earth, even of the Observatories of Greenwich and Paris, are still uncertain to the amount of at least half a second, it will be easily apprehended that the errors of the latitudes are more to be feared than any which can affect the measurement of the base, or the angles, or the direction of the meridian. In the British survey, that of India, and some on the Continent, the latitudes were observed with the zenith sector, an instrument peculiarly adapted to this purpose. Ramsden's zenith sector, made expressly for the determination of the arc of meridian between Dunnose and Clifton, carried a telescope of eight feet in length. With this superb instrument, for a description of which we must refer to the second volume of the *Trigonometrical Survey*, the zenith distances of several of the northern stars were observed at both extremities of the arc; and the difference of two zenith distances of the same star is evidently the same as the difference of the latitudes of the two stations. It may be remarked, that the result of this observation is independent of the declination of the star; and if the observation is made at the second station within a short time after it was made at the first, the result is also nearly independent of the nutation.

For the determination of the French arc of meridian, the latitudes were observed with the repeating circle. This instrument, on account of its portability, is of the greatest use in geodetic operations; but it may be questioned whether it can be safely relied on for the determination of so very important an element as the latitude. Besides the want of power in the telescope, it is found to be affected in some unaccountable way by a constant error, which, however carefully its amount may have been determined, leaves a degree of uncertainty with regard to the results. Mechain mistook the latitude of Barcelona by about 3″. It is to be regretted that the latitudes of Dunkirk and Formentera, the extremities of the French arc, have not been determined with the zenith sector. All the other operations connected with the measurement of that extensive arc have been executed in a style of such decided superiority, that a more satisfactory, if not more accurate, determination of the latitudes is alone wanting to render it the most valuable application of science that has ever been made with a view to ascertain the magnitude and exact figure of our globe.

The measurement of an arc of parallel usually forms part of the operations connected with the survey of a large extent of country. It will frequently happen that the sides of some of the great triangles lie in a direction nearly perpendicular to the meridian, in which case the arc of the terrestrial parallel may be easily computed from an approximate knowledge of the earth's dimensions; and if the difference of longitude of the two stations, or the angle which their respective meridians make with each other, has been accurately determined, the comparison of the corresponding celestial and terrestrial arcs will give the length of the degree on the parallel. By comparing this result with the length of a degree measured on a different parallel, or on the meridian, we can easily deduce the ellipticity.

Perhaps the simplest way of conveying an accurate idea of the nature of the operations necessary to be undertaken in the measurement of an arc of parallel, will be to describe the method that was actually followed in the British trigonometrical survey, in determining the length of an arc of parallel from the measured distance between Beachy Head and Dunnose.

Let BW (fig. 8) be an arc of the great circle perpendicular to the meridian of Beachy Head at B, meeting that of Dunnose in W; and let DR be an arc of the great circle perpendicular to the meridian of Dunnose at D, meeting that of Beachy Head in R; and let BL and DE be the parallels of latitude passing through B and D. It is supposed that the latitudes of the two places have been determined, together with the angles PBD and PDB, which they reciprocally make with each other and the pole; and also that the distance between them on the arc of the great circle has been measured: the question is then to find the difference of their longitudes, or the angle BPD, and the distance in feet between the meridians on the arcs of the small circles BL and DE passing through the places.

In the small spheroidal triangle WBD there were given by observation the two angles WBD and WDB, which being reduced to the angles made by the chords, gave the two angles of the corresponding plane triangle. The side BD was found by triangulation = 339,397·6 feet; whence the chord of the perpendicular arc BW was found = 336,115·6 feet. In like manner the chord of DR was found = 336,980 feet.

The terrestrial distances being thus found, it was next necessary to find the difference of longitude, or the angle P, and the lengths of the arcs of parallel BL and DE in degrees. For this purpose there are given PB the colatitude of B, PD the colatitude of D, the angle PBD, which is the azimuth of D as seen from B, and PDB the azimuth of B as seen from D.

The rigorous solution of this problem on the spheroid is attended with considerable difficulty. An approximation is however easily obtained from a property of spheroidal triangles (for the demonstration of which we must refer to the *Phil. Trans.* vol. lxxx.), namely, that the sum of the horizontal angles on a spheroid (or indeed on any surface differing little from that of a sphere) is *nearly* the same as the sum of those which would be observed on a sphere, the latitudes and difference of longitudes being the same on both figures. Assuming therefore the sum of the two angles PDB and PBD to be the same as the sum of two spherical angles, we have, from Napier's analogies (see TRIGONOMETRY),

$$\cos.\tfrac{1}{2}(\mathrm{PD}+\mathrm{PB}) : \cos.\tfrac{1}{2}(\mathrm{PD}-\mathrm{PB})$$
$$= \cot.\tfrac{1}{2}\,\mathrm{P} : \tan.\tfrac{1}{2}(\mathrm{PDB}+\mathrm{PBD}),$$

whence

$$\tan.\tfrac{1}{2}\,\mathrm{P} = \frac{\cos.\frac{1}{2}(\mathrm{PD}-\mathrm{PB})}{\cos.\frac{1}{2}(\mathrm{PD}+\mathrm{PB})} \times \cot.\tfrac{1}{2}(\mathrm{PDB}+\mathrm{PBD});$$

that is to say, the tangent of half the difference of longitudes is equal to the cotangent of half the sum of the azimuthal angles multiplied into the ratio of the cosine of half the difference of the colatitudes to the cosine of half their sum. In the case under consideration the angle P was found = 1° 26′ 47″·93.

We have now given, in the right-angled triangle PBW, which may be considered as spherical, the side PB and the angle P, whence BW was found = 54′ 56″·21. And from the triangle PDR, in which the side PD and the angle P are given, DR was found = 55′ 4″·74.

The chords of the two perpendicular arcs BW and DR, whose radius is the radius of the earth, are found, from an approximate knowledge of the earth's diameter, to be three feet and a half shorter than the arcs themselves, whence the arc BW = 336,119·1 feet, and DR = 336,983·5 feet. Hence the length of the degree of the great circle perpendicular to the meridian, at the middle point between W and B, is found by proportion = 367,096·8 feet, and in the middle point between R and D = 367,090·8 feet. Therefore the mean, or 367,093·8, is the length of a degree of the great circle perpendicular to the meridian in latitude 50° 41′, which is nearly that of the middle point between Beachy Head and Dunnose.

Now, by reason of the short distance between the two stations, and their small difference in latitude, the two radii of curvature at B and D may be regarded as intersecting each other on the axis at M (fig. 9). Therefore DM is the radius of the great circle perpendicular to the meridian, and DE is the radius of the parallel at D. Therefore 1° of the great circle : 1° of the parallel as DM : DE; and DM : DE = 1 : cos. latitude of D; whence 1 : cos. 50° 44′ 24″ = 367,094 : 232,314 feet for the degree of parallel at Beachy Head, and 1 : cos. 50° 37′ 7″ = 367,094 : 232,914 feet for the degree of parallel at Dunnose. (*Trig. Survey*, vol. i. p. 113.)

The length of the degree of the great circle perpendicular to the meridian, deduced in the manner now explained, is about 1250 feet greater than on the spheroid which corresponds with the measurements of the meridional arcs. This discrepancy gave rise to a suspicion of errors in the observation of the azimuthal angles; and, in fact, the difference of longitude, in order to agree with other determinations, ought to be about 18″ greater than that which was determined in the survey. With this correction the length of the degree of the perpendicular circle is found = 365,838 feet. Assuming the dimensions of the earth deduced from the survey, the length of the degree perpendicular to the meridian at the mean latitude is 365,844 feet. Hence 1° parallel = 231,801 feet.

In the *Philosophical Transactions* for 1824 an account is given of some experiments performed by Dr Tiarks for determining the difference of longitude of Dover and Falmouth. Twenty-four chronometers were transported by sea, three several times, from the one place to the other, by which means the difference of the apparent times was determined. The difference of longitude was thus found to be 6° 22′ 6″; and the length of the parallel, as found from the survey, being 1,474,672 feet, we have the length of a degree of parallel at latitude 50° 44′ 24″ = 231,563 feet.

The most extensive arc of parallel which has yet been measured is that between Marennes (near Bordeaux) and Padua. The details of the operations, which were performed in 1822 and 1823, are given in the *Connaissance de Tems* for 1829. The terrestrial arc was determined by triangulation in the usual manner, and the astronomical amplitude by fire signals observed from station to station at five intermediate stations. There are consequently six independent arcs; and the final result is affected with the accumulated errors at all the stations. The terrestrial distance was found to be 1,010,996 mètres, or 3,316,976 English feet; and the difference of time determined by chronometers 51 min. 56·24 sec., corresponding to 12° 59′ 3″·75 of longitude. The mean length of the degree, found from the partial arc between Marennes and Geneva, is 255,546 feet, and from the whole arc between Marennes and Padua 255,470 feet, both of which results are greater than the degree on the regular spheroid, which is found to represent most nearly the meridional arcs under the same parallel of latitude, namely, 45° 43′ 12″. No great reliance, however, can be placed on this determination, on account of the uncertainty that exists respecting some of the longitudes, the determination of which was found to be attended with great difficulty. If the difference of longitude of Marennes and Padua were found by good astronomical observations, the discrepancies would probably be diminished.

SECTION III.

DETERMINATION OF THE FIGURE OF THE EARTH FROM GEODETIC MEASURES.

Assuming the figure of the earth to be that of an elliptic spheroid of revolution, the magnitude and ratio of its equatorial and polar diameters may be determined from the comparison of the lengths of lines measured between determined points on its surface, with the corresponding arcs of the celestial sphere, by means of theorems which we shall now proceed to demonstrate.

1. *To express the radius of curvature of a meridian in terms of the latitude.*

Let PDQ (fig. 10) be the meridian, CP half the polar axis, CQ the radius of the equator, DM a perpendicular to the tangent at D, meeting CP in M, and CQ in N; and let

a = CP half the polar axis,
b = CQ the radius of the equator,
n = DN the normal at D,
r = radius of curvature at D.

Join CD; let CD′ be the diameter conjugate to CD, meeting DM in G; and through D draw DE and DF respectively perpendicular to CP and CQ. It is demonstrated in the article Conic Sections (Part IV. Sec. 2, Prop. V. Cor. I.), that $r \times$ DG = CD′^{2}; and (Prop. XVII. Part II.) CD′ × DG = CP × CQ = ab; whence CD′^{2} = $a^2 b^2 \div$ DG^2; and consequently $r \times$ DG$^3 = a^2 b^2$. But (Prop. XXI. Part II.) DN × DG = CP^2; that is, $n \times$ DG $= a^2$; whence $n^3 \times$ DG$^3 = a^6$, and therefore DG$^3 = a^6 \div n^3$, consequently

$$r=\frac{b^2 n^3}{a^4}\text{.....................................(1.)}$$

Again (Prop. XXI. Part II.) DN : DM = $a^2 : b^2$; and the triangles NCM, NFD being similar, DN : DM = NF : CF, whence CF = $\frac{b^2}{a^2}$ NF. Now let the angle DNF or the latitude of D = l; then DF = n sin. l, NF = n cos. l, and CF = $\frac{b^2}{a^2} n$ cos. l. But DF = CE = x and CF = y; substituting therefore n sin. l for x, and $\frac{b^2}{a^2} n$ cos. l for y in the equation of the ellipse, namely,

$$\frac{x^2}{a^2}+\frac{y^2}{b^2}=1,$$

we find

$$\frac{n^2\sin.^2 l}{a^2}+\frac{b^2 n^2\cos.^2 l}{a^4}=1,$$

whence

$$n^2=\frac{a^4}{a^2\sin.^2 l+b^2\cos.^2 l}.$$

Let $b = a\,(1 + e)$ (e denoting the ellipticity or the ratio of the difference of the semiaxes to the polar semiaxis, that is, $e=\frac{b-a}{a}$; by substituting, we get

$$n^2=\frac{a^2}{\sin.^2 l+(1+e)^2\cos.^2 l};$$

but since the ellipticity e is very small, all terms multiplied by the square or higher powers of e may be rejected without sensible error. Hence $(1 + e)^2 = 1 + 2\,e$, and therefore $n^2=\frac{a^2}{1+2e\cos.^2 l}$, or $n=a(1+2e\cos.^2 l)^{-\frac{1}{2}}$; whence, on developing and rejecting terms containing e^2,

$$n = a\,(1 - e\cos.^2 l)\text{.........................(2.)}$$

Now, from equation (1), $r=\frac{b^2}{a^4}n^3=\frac{1+2e}{a^2}n^3$; and from equation (2), $n^3 = a^3\,(1 - 3\,e\cos.^2 l)$; therefore $r=a\,(1+2e)\,(1-3e\cos.^2 l)=a\,(1+2e-3e\cos.^2 l)$; or, finally,

$$r = a\,(1 - e + 3\,e\sin.^2 l)\text{.................(3.)}$$

2. *To express the radius of a circle parallel to the equator in terms of the latitude.*

Suppose the parallel to pass through D, then DE = y is the radius required. But it was shown in the last Prop. that CF (= DE) = $\frac{b^2}{a^2} n$ cos. l; therefore, substituting $a^2\,(1 + 2\,e)$ for b^2, we have $y = n$ cos. $l\,(1 + 2\,e)$. Substituting in this the value of n given by equation (2), we have $y = a$ cos. $l\,(1 + 2\,e)\,(1 - e\cos.^2 l)$; whence $y = a$ cos. $l\,(1 + 2\,e - e\cos.^2 l)$, or

$$y = a\cos. l\,(1 + e + e\sin.^2 l)\text{................(4.)}$$

3. *To find an expression for the length of an arc of the meridian, in terms of the latitudes of its extreme points.*

If the arc is small, it may be regarded as coinciding with the osculating circle at its middle point. Let z = the arc, and r = the radius of curvature at its middle point; then (z being supposed small) we have $z = r$ sin. z. But z : sin. z = 1″ : sin. 1″; therefore sin. $z = z$ sin. 1″, and the length of the arc in feet = $r\,z$ sin. 1″. Now let l and l' be the latitudes at the extremities of the arc, then $\frac{1}{2}\,(l + l')$ is the latitude of its middle point; and on substituting for r its value found in equation (3), the expression for the length of a meridional arc, in terms of its extreme latitudes l' and l, is

$$z = a\left\{1-e+3e\sin.^2\tfrac{1}{2}(l+l')\right\}(l'-l)\sin. 1''\text{...(5.)}$$

But if the arc is of considerable extent, this expression will not be sufficiently exact, and it becomes necessary to find by integration the lengths of the arcs from the equator to each extremity of the given arc: the difference of these two will give z itself. At the latitude l, $dz = rdl$; therefore, from equation (3),

$$dz = a\,(1 - e)\,dl + 3\,ae\sin.^2 l\,dl,$$

and integrating,

$$z = al - ael + 3\,ae\int \sin.^2 l\,dl.$$

But $\int \sin.^2 l\,dl = \frac{1}{2}l - \frac{1}{4}\sin.\,2\,l$; therefore

$$z = a\left\{(1+\tfrac{1}{2}e)\,l - \tfrac{3}{4}e\sin.\,2\,l\right\}\ldots\ldots\ldots\ldots\ldots(6.)$$

No constant is necessary, because at the equator z and l vanish together.

Let z' be another arc reckoned from the equator to the point whose latitude is l'; then, similarly,

$$z' = a\left\{(1+\tfrac{1}{2}e)\,l' - \tfrac{3}{4}e\sin.\,2\,l'\right\};$$

and consequently

$$z' - z = a\left\{(1+\tfrac{1}{2}e)(l'-l) - \tfrac{3}{4}e(\sin.\,2\,l' - \sin.\,2\,l)\right\};$$

but $\sin.\,2\,l' - \sin.\,2\,l = 2\cos.\,(l'+l)\sin.\,(l'-l)$; therefore

$$z' - z = a\left\{(1+\tfrac{1}{2}e)(l'-l) - \tfrac{3}{2}e\cos.\,(l'+l)\sin.\,(l'-l)\right\},$$

or, as $l'-l$ is expressed in seconds, $z'-z$

$$= a\left\{(1+\tfrac{1}{2}e)(l'-l)\sin.\,1'' - \tfrac{3}{2}e\cos.(l'+l)\sin.(l'-l)\right\}(7.)$$

4. *To express the length of an arc of parallel in terms of the radius.*

Let $y =$ the radius, D $=$ the amplitude of the arc in seconds, and V $=$ its length in feet. Then, by what is shown above, the length of the arc in feet is $y\mathrm{D}\sin.\,1''$. Hence, from the value of y given in equation (4), the length of the arc of parallel at latitude l is

$$\mathrm{V} = a\cos.\,l\,(1+e+e\sin.^2 l)\,\mathrm{D}\sin.\,1''\ldots\ldots\ldots\ldots(8.)$$

5. *From the measured length of two degrees of meridian at different latitudes, to determine the axis and ellipticity of the spheroid.*

Let Z and Z′ be the measured lengths of two degrees, and the latitudes of their middle points be respectively L and L′; then (since in this case $l'-l = 1° = 3600''$) we have, by equation (5),

$$\mathrm{Z} = a\,(1 - e + 3\,e\sin.^2\mathrm{L})\,3600\sin.\,1'',$$
$$\mathrm{Z}' = a\,(1 - e + 3\,e\sin.^2\mathrm{L}')\,3600\sin.\,1'',$$

therefore

$$\frac{\mathrm{Z}'}{\mathrm{Z}} = \frac{1 - e + 3\,e\sin.^2\mathrm{L}'}{1 - e + 3\,e\sin.^2\mathrm{L}};$$

whence, performing the division, and neglecting terms multiplied by e^2,

$$\frac{\mathrm{Z}'}{\mathrm{Z}} = 1 + 3\,e\,(\sin.^2\mathrm{L}' - \sin.^2\mathrm{L}),$$

from which we find the ellipticity

$$e = \frac{\mathrm{Z}' - \mathrm{Z}}{3\,\mathrm{Z}\,(\sin.^2\mathrm{L}' - \sin.^2\mathrm{L})}\ldots\ldots\ldots\ldots\ldots\ldots(9.)$$

The accuracy of this expression will depend on the magnitude of the denominator, or the difference between L′ and L. If L is nearly equal to L′, the denominator becomes very small, and the value of e in consequence uncertain. The most favourable determination, therefore, that can be obtained is, when one of the degrees, Z′, for example, is measured near the pole, and Z at the equator, where L is zero. As an example of this method, we may deduce the value of e from a comparison of the lengths of a degree at the equator and in England. Bouguer found the length of the degree at the equator to be 362,932 English feet; and from the British arc, between Dunnose and Clifton, the length of the degree is 364,970 feet, at the latitude of 52° 35′ 45″. We have therefore Z $=$ 362,932, Z′ $=$ 364,970, L $=$ 0, L′ $=$ 52° 35′ 45″, by substituting which in equation (9), there results

$$e = \frac{2038}{3 \times 362932 \times \sin.^2(52°\,35'\,45'')},$$

whence $e = \frac{1}{346}$.

Having found the value of e, that of the polar semi-diameter, or a, is obtained as follows. At the equator, where L vanishes, we have $\mathrm{Z} = a\,(1-e)\,3600\sin.''$, whence

$$a = \frac{\mathrm{Z}}{(1-e)\,3600\sin.\,1''} = \frac{\mathrm{Z}\times 346}{345\times 3600\sin.''};$$

and substituting 362,932 for Z, we find

$a =$ 20,855,000 feet nearly.

The method of deducing the ellipticity and dimensions of the earth which has now been explained, may be conveniently employed when the measured arcs are small; but when the arcs are considerable (and it is necessary that they should extend over several degrees, in order to give results deserving of confidence), we must employ the more accurate expression of the arc found in equation (7); that is to say, we must employ the whole arc measured, instead of the resulting length of a single degree. Equation (7), when reduced to numbers, takes the form

$$\mathrm{A} = am + aen\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(10.)$$

in which m, n, and the arc A, are numbers determined by observation. Another arc will give a similar equation,

$$\mathrm{A}' = am' + aen',$$

and by combining the two equations we get

$$e = \frac{\mathrm{A}m' - \mathrm{A}'m}{\mathrm{A}'n - \mathrm{A}n'};\quad a = \frac{\mathrm{A}n' - \mathrm{A}'n}{mn' - m'n}\ldots\ldots\ldots\ldots\ldots\ldots(11.)$$

If the terrestrial meridian were a regular ellipse, the ellipticity deduced from two measured arcs would be the same at every latitude. But it is found that no two different measures that have yet been effected concur in giving exactly the same figure to the meridian. Hence it becomes necessary to seek the most probable mean among the different results. Each new measure affords a new equation of condition, of the form of equation (10); and as the number of unknown quantities remains the same, whatever may be the number of equations, recourse must be had to the method of least squares, or some of the other methods of combination employed by astronomers. In this way each individual measurement serves to correct the results given by the former ones.

6. *From the measured lengths of an arc of meridian, and an arc of parallel, to determine the ellipticity of the spheroid.*

Let z be the arc of meridian between the latitudes l and l', V the length of the arc of parallel in feet at the latitude L, and D the difference of longitude in seconds between its extreme points. From equation (5) we have

$$z = a\left\{1 - e + 3\,e\sin.^2\tfrac{1}{2}(l'+l)\right\}(l'-l)\sin.\,1'',$$

and from equation (8),

$$\mathrm{V} = a\,(1 + e + e\sin.^2\mathrm{L})\cos.\,\mathrm{L}\times\mathrm{D}\sin.\,1'',$$

whence

$$\frac{\mathrm{V}}{\cos.\,\mathrm{L}\times\mathrm{D}\sin.\,1''} - \frac{z}{(l'-l)\sin.\,1''}$$
$$= ae\left\{2 + \sin.^2\mathrm{L} - 3\sin.^2\tfrac{1}{2}(l'+l)\right\},$$

and, consequently,

$$e = \frac{\dfrac{\mathrm{V}}{\cos.\,\mathrm{L}\times\mathrm{D}\sin.\,1''} - \dfrac{z}{(l'-l)\sin.\,1''}}{a\left\{2 + \sin.^2\mathrm{L} - 3\sin.^2\tfrac{1}{2}(l'+l)\right\}}\ldots\ldots\ldots\ldots(12.)$$

When the two arcs have been measured at the same

Figure of the Earth.

of latitude, that is, when $L = \frac{1}{2}(l' + l)$, the denominator of this fraction becomes $a\,(2 - 2\,\sin.^2 L) = 2\,a\,\cos.^2 L$. This combination may be considered as giving a correct representation of the curvature at any particular place, or of the dimensions and eccentricity of the osculating spheroid at that place. But, speaking generally, the exact determination of the differences of longitude is attended with so much uncertainty, that the results obtained from the comparison of arcs of parallel, either with one another or with arcs of meridian, cannot be relied on with much confidence. It is consequently unnecessary to point out the equations to be employed in deducing the ellipticity from the comparison of two arcs of parallel.

We shall now proceed to apply the above formulas to the results of the principal geodetic measurements that have been executed in different countries. The following table contains twenty arcs of meridian, between the equator and 66° of north latitude; and as they have all been determined with the utmost attention to every circumstance which could be supposed to affect their accuracy, they may be regarded as decidedly the best elements we yet possess for the solution of the problem of the figure of the earth. We have excluded all the ancient arcs except that of Bouguer, and also some recent ones, where the locality was unfavourable. They are all reduced to the level of the sea. In reducing the foreign measures, the metre has been assumed (according to Captain Kater's determination) = 3·280899 feet, and the toise = 6·394596 feet, of Schuckburgh's scale. The original documents are given in the various works to which reference has been made in the first section of this article.

Substituting in equation (7) the values of $z' - z$, l, and l', for each of the arcs in the above table, we obtain the following equations of condition:

1. $a \times {\cdot}0544111 - ae \times {\cdot}05426 = 1131057$
2. $a \times {\cdot}0276169 - ae \times {\cdot}02371 = 574368$
3. $a \times {\cdot}0495037 - ae \times {\cdot}04536 = 1029171$
4. $a \times {\cdot}0716119 - ae \times {\cdot}06058 = 1489198$
5. $a \times {\cdot}0515924 - ae \times {\cdot}03891 = 1073409$
6. $a \times {\cdot}0531157 - ae \times {\cdot}03519 = 1105499$
7. $a \times {\cdot}0527472 - ae \times {\cdot}02933 = 1097320$
8. $a \times {\cdot}0470778 + ae \times {\cdot}01131 = 982247$
9. $a \times {\cdot}0323260 + ae \times {\cdot}01159 = 674623$
10. $a \times {\cdot}0517210 + ae \times {\cdot}02504 = 1079706$
11. $a \times {\cdot}0465751 + ae \times {\cdot}02940 = 973853$
12. $a \times {\cdot}0381990 + ae \times {\cdot}02893 = 798971$
13. $a \times {\cdot}0077158 + ae \times {\cdot}00636 = 161412$
14. $a \times {\cdot}0280221 + ae \times {\cdot}02335 = 586319$
15. $a \times {\cdot}0215422 + ae \times {\cdot}01900 = 450018$
16. $a \times {\cdot}0194397 + ae \times {\cdot}01875 = 406516$
17. $a \times {\cdot}0351849 + ae \times {\cdot}03132 = 736426$
18. $a \times {\cdot}0327868 + ae \times {\cdot}03708 = 686022$
19. $a \times {\cdot}0297797 + ae \times {\cdot}03618 = 623719$
20. $a \times {\cdot}0283097 + ae \times {\cdot}04293 = 593278$

From any two of these equations we may deduce values of a and e; but, as might be expected, the results are found to be very different according as different arcs are selected for comparison. We may also add any number of the equations together, for instance Nos. 3, 4, 5, 6, and 7, the sum of which forms the continuous arc measured in India by Colonel Lambton and Captain Everest: or Nos. 8, 9, 10, 11, and 12, which form the French arc from Dunkirk to Formentera. But as it is impossible to satisfy at once all the equations by any value whatever that can be assigned to a and e, in order to exclude all arbitrary hypotheses, it is necessary to suppose all the observations to have been alike good, and deduce values of a and e from a combination of the whole. The best method of effecting the combination is that of *minimum squares*, the principle of which is contained in the following rule: Multiply all the terms of each of the proposed equations by the co-efficient of a in that equation, taken with its proper sign, and make the sum of all the products equal to zero. This will give an equation in which the sum of the squares of the errors is a minimum in respect of a. Multiply then each equation by the co-efficient of ae in that equation, and make the sum of all the products $= 0$. This will give a second equation, in which the sum of the squares of the errors is a minimum in respect of ae. From the two equations thus obtained, the values of a and ae, and consequently e, are found in the usual manner. The operation is extremely laborious when the equations are numerous, but it is attended with no difficulty.

By combining the above twenty equations in the manner now described, M. Schmidt obtained the following results, which are given in No. 213 of Schumacher's *Astronomische Nachrichten*, p. 371; and they are unquestionably entitled to be regarded as the best determination of the magnitude and figure of the earth which has been found from the operations that have been undertaken up to the present time for the measurement of meridional arcs.

Radius of equator $= b = 20921665$ Eng. feet.

Radius of pole..... $= a = 20852394$

$$\text{Ellipticity} = e = \frac{b-a}{a} = \frac{1}{301{\cdot}02} = {\cdot}0032555$$

Degree at equator..... = 362732

Degree at latitude 45° = 364543·5

In order to discover how nearly the different measures agree with a spheroid having the dimensions now given, we shall compare the length of a degree, as given by each of the above twenty arcs, with its length, computed from these values of a and e at the same latitudes.

No.	Latitude of Middle Point.			Measured Length of Degree.	Computed Length of Degree.	Error in Measure.
1	— 1°	31′	0″	362,809	362,736	+ 73

17	52	32	17	365,301	365,019	+ 282
18	57	26	26	365,203	365,310	— 107
19	59	13	58	365,551	365,412	+ 139
20	66	20	11	365,697	365,777	— 80

From this table we see that the degrees increase gradually from the equator to the pole; but the increase is by no means regular. It occurs in some instances that the degrees appear to diminish on going northward; but these anomalies must be ascribed either to errors in the observations or to local irregularity of form or density. The most probable source of error is in the latitudes, first, on account of the difficulty of the observation to the requisite degree of accuracy; and, secondly, on account of the irregularities in the density of the exterior crust of the earth, which cause a deflexion of the plumb-line from the true zenith. Hence the longest arcs are the best; for the probable error in the determination of the difference of latitudes is the same whether the arcs are great or small. An error of 1″ in the latitude corresponds to about a hundred feet on the ground.

If we compare the degree found by some of the measures which have been rejected from the foregoing table, with the degree computed for the same latitudes, we shall find the errors or anomalies much greater.

Arcs.	Lat. of Middle Point.			Measured Length of Degree.	Computed Length of Degree.	Difference.
Lacaille's arc at Cape of Good Hope..........................	—33°	18′	30″	364,712	363,826	+ 886
North American arc, by Mason and Dixon....................	39	12	00	363,786	364,181	— 395
Roman arc, by Boscovich...	42	59	00	364,262	364,418	— 156
Piedmontese arc, by Plana and Carlini........................	44	57	30	368,242	364,543	+ 3699
Maupertuis' Swedish arc...	66	19	37	367,086	365,774	+ 1312

Two of these differences are considerably greater than any in the preceding table. Lacaille's arc corresponds to one in the northern hemisphere at a higher latitude by 11°, whence it has been inferred that the two hemispheres are not exactly similar. The measurement of Plana and Carlini appears to have been excellent; but both extremities of the arc were in the immediate vicinity of lofty mountain ranges, and the very great deviation from the mean result of the other measures can only be accounted for by the disturbing effects of local attraction. Maupertuis' arc was never reckoned of much value, as it was evident from the first that there was an error in the determination of the latitudes.

Taking the results of the four arcs of parallel mentioned before, and computing the corresponding degree from the formula $a \cos. l\,(1 + e + e \sin.^2 l)\; 3600 \sin. 1''$ (supposing a and e to have the same values as above), we get the following table:

Arcs of Parallel.	Latitude.	Measured Degree.	Computed Degree.	Difference.
Lacaille's arc across the mouth of the Rhone	43° 31′ 50″	266,345	265,154	+ 1191
Roy's arc from Beachy Head to Dunnose	50 44 24	232,331	231,542	+ 789
Arc from Dover to Falmouth	50 44 24	231,579	231,542	+ 37
Arc from Padua to Marennes	45 43 12	255,480	255,370	+ 110

It is remarkable that all these errors are affected with the same sign; and the circumstance might seem to strengthen a conclusion indicated by a comparison of the errors of the meridional arcs, namely, that the meridional curve is not exactly an ellipse, but protuberant between the latitudes of 40° and 52°; in consequence of which the degrees of meridian are shorter, and the degrees of parallel longer between those latitudes, than if the earth were a regular ellipsoid. There is no reason to infer that the meridians are not similar, or that the earth is not a solid of revolution.

The six partial arcs into which the whole arc from Marennes to Padua was divided, give the following results (*Connaissance des Tems*, 1829).

	Arcs.	Astronomical Amplitudes.	Length in Feet.	Length of Degree.
		h. m. sec.		
1	Marennes to St Preuil	0 3 48·99	244,123	255,865
2	St Preuil to Sauvagnac	0 6 23·09	407,429	255,248
3	Sauvagnac to Isson	0 6 51·39	437,493	255,228
4	Isson to Geneva	0 11 57·82	764,736	255,686
5	Geneva to Milan	0 12 9·57	776,646	255,486
6	Milan to Padua	0 10 45·38	686,549	255,308

The mean of these results, or the most probable value of the degree of parallel at the latitude of the stations (45° 43′ 12″), is 255,470 feet, exceeding the computed length only by a hundred feet; and the ellipticity which they indicate is $\frac{1}{282{\cdot}8}$. This is considerably greater than the ellipticity indicated by the measures of meridional arcs, but agrees pretty nearly with that which we shall see is given by the pendulum observations. The results, however, though valuable as confirming the results obtained by other methods, are not by any means worthy of the same confidence as those deduced from the measurement of meridional arcs.

We shall conclude this section with a re-statement of the dimensions of the earth, resulting from the principal measures of arcs of meridian.

		Feet.		Miles.
Equatorial diameter	=	41843330	=	7924·873
Polar diameter	=	41704788	=	7898·634
Difference of diameters, or polar compression	=	138542	=	26·239
Ratio of diameters	=	302·026	:	301·026

$$\text{Ellipticity} = \frac{b - a}{a} = \frac{1}{301{\cdot}026}$$

Length of degree at equator = 362732 feet.
Length of degree at lat. 45° = 364543·5 feet.

SECTION IV.

THEORETICAL INVESTIGATION OF THE FIGURE OF THE EARTH FROM THE LAWS OF HYDROSTATICS.

In attempting to deduce the figure of the earth from the general laws of hydrostatic equilibrium, we suppose the whole mass to have been originally fluid, or in such a state, that all its molecules were at liberty to obey the forces by which they are impelled. These forces are, 1*st*, the attraction of the molecules on one another, according to the Newtonian law; and, 2*dly*, the centrifugal force generated by the revolution of the whole mass about a fixed axis; and the problem is, to determine the form which such a body, under the influence of these forces, would ultimately take. In order to obtain a solution of the question thus generally enunciated, it is necessary to know, *a priori*, the attractions of the different parts of the fluid body on one another. But the attraction of its different parts depends on their mutual arrangement; that is to say, on the internal constitution of the body or the variations of its density, and also on its form. Of the density in the interior of the earth we know little; and its form is the very element we are seeking to determine. This mutual dependence of the attraction of the mass on its form, and of its form on its attraction, renders it necessary to have recourse to certain arbitrary assumptions respecting the primitive figure of the earth and its internal structure, in order to determine the relation of the forces with which its different parts attract each other, and thence assign its figure, and the variations of gravity at the different points of its surface.

A fluid mass whose particles are impelled by no other forces than those which result from their mutual attractions, would assume (it is natural to suppose) a spherical form. Such at least would be a figure of equilibrium; for the surface of the sphere being everywhere at right angles to the directions of the attracting forces, which in this case all pass through the centre of gravity, a particle placed on its surface would have no tendency to move along the surface in any direction. But if the mass is made to revolve, the rotation gives rise to an extraneous force, tending to cause every particle to recede from the axis, and which acts with an energy on each particle directly proportional to the distance of the particle from the axis. Hence the attraction of the mass on each particle, in the direction perpendicular to the axis of rotation, is diminished, and the diminution is greatest towards the equatorial parts, where the distance from the axis is greatest. In order, therefore, that the equilibrium may be restored, an accumulation of matter must take place about the equator, so that the mass will bulge out in that quarter, and become flattened at the poles, where the force of attraction is not counteracted. This consideration led Newton to suppose the figure of the earth to be that of an oblate spheroid, or the figure that is generated by the revolution of an ellipse about its shorter axis.

Before proceeding with the investigation, it will be proper to inquire what are the conditions necessary to ensure the equilibrium of a mass of fluid matter, the particles of which are acted on by their mutual attractions and the centrifugal force of rotation. Conceive the particles of a body A to be solicited by accelerating forces of any kind. Suppose dm (which may be regarded as a rectangular parallelepipedon, having its faces parallel to the planes of the co-ordinates) to be one of the molecules of the mass, and x, y, z, the co-ordinates of the solid angle nearest the origin; then, putting $k =$ the density of the mass, we shall have $dm = k \,.\, dx\, dy\, dz$. Let X, Y, Z be the accelerating forces acting on dm in the direction parallel to the respective axes of the co-ordinates, then the motive forces in the direction of the same axes will be respectively $\mathrm{X}dm$, $\mathrm{Y}dm$, $\mathrm{Z}dm$.

Now let $p =$ the pressure in the direction of the axis of x, referred to the unit of surface; then $p \,.\, dydz$ is the whole pressure on the face $dydz$ of the element dm. But p may be regarded as a function of x, y, z; therefore at the point whose co-ordinates are $x + dx, y, z$, the pressure on the unit of surface is $p + \frac{dp}{dx}dx$, and consequently the whole pressure on the face of dm opposite to $dxdy$ is $\left(p + \frac{dp}{dx}dx\right) dydz$. The particle dm is thus urged in the direction of the axis of x by the two forces $p \,.\, dydz$ and $\left(p + \frac{dp}{dx}dx\right) dydz$, or by a force equal to their difference, namely, $\frac{dp}{dx}dxdydz$. In order, therefore, that dm may remain at rest, this last force or pressure must be exactly balanced by the motive force acting in the direction of the same axis; that is to say, we must have $\frac{dp}{dx}dxdydz = \mathrm{X}dm$. In the same manner, we must have $\frac{dp}{dy}dxdydz = \mathrm{Y}dm$, and $\frac{dp}{dz}dxdydz = \mathrm{Z}dm$; whence, since $dm = k \,.\, dx\, dy\, dz$, we deduce

$$\frac{dp}{dx} = k\mathrm{X},\ \frac{dp}{dy} = k\mathrm{Y},\ \frac{dp}{dz} = k\mathrm{Z}\ldots\ldots\ldots\ldots(a).$$

Let the first of these equations be multiplied by dx, the second by dy, and the third by dz, the sum of the products gives

$$dp = k\,(\mathrm{X}dx + \mathrm{Y}dy + \mathrm{Z}dz)\ldots\ldots\ldots\ldots\ldots(b).$$

The first member of this equation being an exact differential, it is necessary, in order that the equilibrium be possible, that the second member be an exact differential likewise. This, therefore, is a condition which must be satisfied.

At the surface of the mass the pressure p vanishes, and equation (b) becomes

$$0 = k\,(\mathrm{X}dx + \mathrm{Y}dy + \mathrm{Z}dz),$$

which expresses that the resultant of the three forces X, Y, Z, is perpendicular to the surface.

If the fluid is homogeneous, the density k is constant, and may be represented by unit. In this case equation (b) becomes

$$dp = \mathrm{X}dx + \mathrm{Y}dy + \mathrm{Z}dz,$$

and the equation of the surface is

$$\int(\mathrm{X}dx + \mathrm{Y}dy + \mathrm{Z}dz) = \text{constant}.$$

It will be remarked that this last equation does not belong merely to the exterior surface or to the homogeneous fluid: by giving a different value to the constant it will form the equation of any surface in the interior of a mass of heterogeneous fluid, at every point of which the pressure or the density is the same. For let the second member of equation (b) be a complete differential, and equal to kdf. We have then $dp = kdf$, whence k is necessarily a function of p and f. But on integrating the equation, f will be given in a function of p, consequently k must be a function of p. When therefore k is constant, p must be constant, or $dp = 0$; hence

$$\int(\mathrm{X}dx + \mathrm{Y}dy + \mathrm{Z}dz) = \text{constant}.$$

The different surfaces defined by this equation all possess the common property of intersecting at every point the resultant of the accelerating forces X, Y, Z at right angles; hence they are denominated *level surfaces.*

It follows, therefore, that when the above equation is satisfied, two conditions necessary to the equilibrium are fulfilled; namely, that the resultant of all the forces urging any particle in the interior of the mass is perpendicular to the level surface passing through that particle; and that the force acting on any particle of the surface is perpendicular to the surface. When the fluid is homogeneous, or the density equal throughout the mass, the first of these conditions is always satisfied, and the second is of itself sufficient. Writers on this subject have therefore in general considered that all the conditions necessary to ensure the equilibrium of a fluid mass, whether homogeneous or heterogeneous, revolving about a fixed axis, are comprehended in the single equation

$$\int(\mathrm{X}dx + \mathrm{Y}dy + \mathrm{Z}dz) = \text{constant};$$

and this is the view which has been taken of the question by Clairaut, D'Alembert, Lagrange, Laplace, Legendre, and Poisson. It has, however, been demonstrated by Mr Ivory, in an elaborate paper in the *Philosophical Transactions for* 1824, that when, as in the case of the earth, a mutual attraction exists among the constituent molecules of the mass, another condition must be fulfilled; and that the equilibrium will not necessarily take place, unless the figure of the mass is such, that any "interior body of the fluid, bounded by a level surface, be *in equili-*

brio with respect to the attraction of all the exterior matter." Hence, in addition to the equation derived from the principle of equal pressure in all directions, a second equation must be satisfied, in virtue of which every level stratum must possess such a figure as to attract all particles in the inside with equal force in opposite directions. Without having regard to this condition, the problem cannot be completely solved. (See also *Philosophical Magazine* for April 1825.)

Within the limits to which the present article must necessarily be confined, it would be in vain to attempt to give a general solution of this very intricate problem. We shall therefore content ourselves with demonstrating that all the conditions of equilibrium will be satisfied, if the figure of the earth (assumed to be fluid) is that of a spheroid of revolution of small ellipticity. We shall, first, suppose the fluid to be homogeneous; and, secondly, that its density is variable.

Prop. I.—A particle placed anywhere within a hollow solid of homogeneous matter, generated by the annular space comprised between two similar and similarly situated concentric ellipses revolving about their common axis, is attracted by the solid equally in all directions.

For let p (fig. 11) be such a particle, and ab any straight line passing through p, meeting the exterior surface in a and b, and the interior in c and d; then if ab be bisected in e, cd will also be bisected in e, because the figures are similar and similarly situated. Therefore $ac = db$. Now conceive ab to be the axis of two opposite pyramids having their vertices at p, and terminated by the surface at a and b, and let mn be an infinitely thin slice of the pyramid ab, formed by surfaces parallel to that of the given spheroid. The attraction of mn on p is directly as the surface mn and inversely as pm^2; but the surface mn is proportional to pm^2; therefore the attraction of p on the pyramidal slice mn is constant; hence the attraction of p on the whole frustum between a and c is proportional to the number of such slices, or to ac. In the same manner the attraction of p on the frustum between d and b is proportional to db. But $ac = db$; therefore p is attracted equally in both directions. The same thing being true of all other pyramids which have their vertices at p, it follows that the particle p is attracted equally in all directions, or remains at rest.

This property, which is true also of the sphere, and forms one of the necessary conditions of equilibrium, was first demonstrated by Newton in the *Principia*.

Prop. II.—To find the ratio of the axes of a homogeneous spheroid of revolution, when a fluid column from the equator to the centre balances the column from the pole to the centre, the spheroid being supposed to revolve about its minor axis, and its particles to attract one another with forces varying in the inverse ratio of their mutual distances.

Let PQ (fig. 12) be a meridian of the spheroid, of which the centre is C. Let us assume in the following propositions,

$\mathrm{P} =$ the attraction of the spheroid at the pole, or gravity,
$\mathrm{Q} =$ the attraction at the equator,
$\varphi =$ the centrifugal force at the equator,
$\mathrm{Q}' = \mathrm{Q} - \varphi$ the gravitation at the equator, or the attraction of the spheroid there diminished by the centrifugal force.

Let also

$a =$ CP half the polar axis,
$b =$ CQ the radius of the equator.

In CP take any point E, and make $\mathrm{CE} = x$. It is demonstrated in the article Attraction (art. 8), that the force with which a particle at E is attracted towards C, is to that with which a particle at P is attracted in the same direction as CE to CP, or x to a; therefore the force at $\mathrm{E} = \mathrm{P}\cdot\frac{x}{a}$. Now if we suppose the area of a section of the column perpendicular to the axis $= 1$, the mass of the element of the column will be $1 \times dx = dx$, and its pressure will consequently be $\mathrm{P}\frac{x}{a}dx$. Let this quantity be represented by du. On integrating, and observing that while x increases u diminishes, we find

$$u = \text{const.} - \mathrm{P}\cdot\frac{x^2}{2a}.$$

At the surface $u = 0$ and $x = a$; therefore

$$0 = \text{const.} - \mathrm{P}\cdot\frac{a^2}{2a};$$

whence, by subtraction, $u = \mathrm{P}\cdot\frac{a^2 - x^2}{2a}$,

and consequently at the centre, where $x = 0$, $u = \mathrm{P}\cdot\frac{a}{2}$.

In like manner, if in CQ we take a point F, and make $\mathrm{CF} = y$, the force at F resulting from the attraction of the spheroid will be $\mathrm{Q}\cdot\frac{y}{b}$. But the centrifugal force at F is to that at Q as CF to CQ, or as y to b; therefore the centrifugal force at $\mathrm{F} = \varphi\cdot\frac{y}{b}$. Hence the force with which a particle at F is attracted towards the centre is $(\mathrm{Q} - \varphi)\frac{y}{b} = \mathrm{Q}'\frac{y}{b}$, and the pressure of the element of the column $= \mathrm{Q}'\frac{y}{b}dy$. Putting this $= du'$, and integrating as before, we find, at the centre, $u' = \mathrm{Q}'\frac{b}{2}$. But, by hypothesis, at the centre $u' = u$; therefore $\mathrm{P}\frac{a}{2} = \mathrm{Q}'\frac{b}{2}$, whence $\mathrm{P} : \mathrm{Q}' = b : a$; that is to say, the attraction at the pole is to the gravitation at the equator as the radius of the equator to the radius of the pole.

Prop. III.—If the radius of the equator is to the radius of the pole as the attraction at the pole is to the gravitation at the equator, the resultant of all the forces which urge a particle situated any where on the surface of the spheroid is perpendicular to the surface.

Let D (fig. 10) be the particle, and PDQ the meridian passing through it. As the plane of the meridian divides the solid into two parts exactly alike in every respect, it is obvious that the particle can have no tendency to move out of that plane; we shall therefore only consider the direction of the force urging it in the plane of the meridian. Let DE be perpendicular to CP, and DF to CQ; and make $\mathrm{CE} = x$, $\mathrm{CF} = y$. It is demonstrated in the article Attraction (21 and 22), that the force which attracts D in the direction DF, perpendicular to the plane of the equator, is to the force at the pole as DF to CP, or as $x : a$; and that the force attracting D in the direction DE perpendicular to the axis is to the attraction at Q as DE to CQ, or as $y : b$; but the centrifugal force at D, which also acts in the direction DE, is to that at Q as DE to CQ; therefore, taking X to represent the whole force at D in the direction parallel to the axis, and Y that in the direction perpendicular to the axis, we have

$$\mathrm{X} : \mathrm{P} = x : a, \text{ and } \mathrm{Y} : \mathrm{Q}' = y : b,$$

Figure of the Earth.

whence $X = P\frac{x}{a}$, $Y = Q'\frac{y}{b}$. In QC take the point N such that FN : FD = Y : X; then FN : FD $= Q'\frac{y}{b} : P\frac{x}{a}$, or FN · x : FD · y = Q$'a$: Pb, whence, since FD = x, and FC = y, FN : FC = Q$'a$: Pb. But by hypothesis Q$'$: P = $a : b$, therefore FN : FC = $a^2 : b^2$, whence by the well-known properties of the ellipse FN is the subnormal, and DN the normal or perpendicular to the surface of the spheroid at D.

Corollary. If the attraction at the pole is represented by CP, then the force at any point D on the surface, in the direction perpendicular to the surface, is proportional to DN the normal passing through D. It is also proportional to DM (the normal produced till it meets the axis); for, by conic sections, DM : DN = $b^2 : a^2$; that is, DM has to DN a constant ratio.

The proposition which has now been demonstrated is sufficient for the equilibrium of a homogeneous fluid mass revolving about an axis. It may, however, be shown directly, that when the above condition is fulfilled, any particle in the interior of the mass will be equally urged in all directions, or will remain at rest. Thus:—

Prop. IV.—If the radius of the equator is to the radius of the pole as the attracting force at the pole is to gravitation at the equator, the pressure which any point D in the interior of the spheroid sustains from the fluid in canals of any form, extending from that point to the surface, is the same for every canal.

Let DD$'d$ (fig. 13) be a canal drawn from any point D in the interior of the spheroid to D$'$ and d in the surface. Let x', y', z' be the rectangular co-ordinates of D, and x'', y'', z'' those of D$'$. Take F and f, any two points in the canal indefinitely near each other, and let x, y, z be the co-ordinates of F; then $x + dx$, $y + dy$, and $z + dz$ are those of f. Now X, Y, and Z being the resultants of the forces acting on F in the directions of the co-ordinates, the forces X, Y, Z will be reduced to the direction of the canal at F by multiplying them respectively by the cosines of the angles which that direction makes with the axes, that is, by $\frac{dx}{du}$, $\frac{dy}{du}$, $\frac{dz}{du}$, (u representing the canal). Hence the accelerating force acting on F in the direction of the canal is $X\frac{dx}{du} + Y\frac{dy}{du} + Z\frac{dz}{du}$; and supposing the area of a section of the canal = 1, the pressure produced by the action of this force on the fluid contained in the portion of the canal Ff is $du\left(X\frac{dx}{du} + Y\frac{dy}{du} + Z\frac{dz}{du}\right)$. But, by what has been demonstrated in the article Attraction (9), $X = P\frac{x}{a}$, $Y = Q'\frac{y}{b}$, $Z = Q'\frac{z}{b}$; therefore, denoting the whole pressure of the canal on F by p, and observing that p diminishes as F is nearer the surface, we have

$$-dp = du\left(P\frac{x}{a}\cdot\frac{dx}{du} + Q'\frac{y}{b}\cdot\frac{dy}{du} + Q'\frac{z}{b}\frac{dz}{du}\right),$$

and integrating,

$$p = \text{const.} - P\frac{x^2}{2a} - Q'\frac{y^2 + z^2}{2b}$$

At the point D this becomes

$$p = \text{const.} - P\frac{x'^2}{2a} - Q'\frac{y'^2 + z'^2}{2b},$$

and at D$'$, where $p = 0$,

$$0 = \text{const.} - P\frac{x''^2}{2a} - Q'\frac{y''^2 + z''}{2b};$$

therefore, by subtraction,

$$p = P\frac{x''^2 - x'^2}{2a} + Q'\frac{y''^2 - y'^2 + z''^2 - z'^2}{2b}.$$

Now the equation of the surface of the spheroid gives

$$x''^2 = \frac{a^2}{b^2}\left\{b^2 - (y''^2 + z''^2)\right\},$$

whence

$$P\frac{x''^2}{2a} = P\frac{a}{2} - P\frac{a(y''^2 + z''^2)}{2b^2},$$

and, by hypothesis, P : Q$'$ = $b : a$, or Pa = Q$'b$; therefore

$$P\frac{x''^2}{2a} = P\frac{a}{2} - Q'\frac{y''^2 + z''^2}{2b};$$

and on substituting this in the above expression of the value of p, we get, finally,

$$p = P\frac{a}{2} - P\frac{x'^2}{2a} - Q'\frac{y'^2 + z'^2}{2b}.$$

This equation being independent of the form of the canal, and of the situation of the point D$'$, will necessarily be the same for every canal extending from D to the surface of the spheroid; consequently the point D sustains the same pressure in all directions.

From what has now been demonstrated, it appears that a fluid spheroid of uniform density, revolving about its lesser axis, and whose particles attract one another with forces varying in the inverse ratio of the distances, will be *in equilibrio* when the gravity at the pole is to the gravity at the equator diminished by the centrifugal force there, as the equatorial axis to the polar axis. The equation of equilibrium of such a spheroid is therefore Pa=Q$'b$; and from this we shall now proceed to determine the ratio of the axes, or of $a : b$, corresponding to a given velocity of rotation.

Let ε be the eccentricity, that is, let $\varepsilon^2 = \frac{b^2 - a^2}{a^2}$, whence $b^2 = a^2(1 + \varepsilon^2)$. It is demonstrated in the article Attraction (23 and 24), that

$$P = 4\pi a\frac{1 + \varepsilon^2}{\varepsilon^3}(\varepsilon - \text{arc tan. } \varepsilon)$$

$$Q = (Q' + \varphi) = 2\pi b\frac{1 + \varepsilon^2}{\varepsilon^3}\left(\text{arc tan. } \varepsilon - \frac{\varepsilon}{1 + \varepsilon^2}\right),$$

the density of the mass being 1, and π the semicircumference of a circle whose radius is unit. Now if t denote the time of a revolution, we shall have, from the theory of central forces, $\varphi = \frac{4\pi^2}{t^2}b$; and making $\frac{\pi}{t^2} = m$, we get $\varphi = 4\pi bm$, whence

$$Q' = 2\pi b\left\{\frac{1 + \varepsilon^2}{\varepsilon^3}\left(\text{arc tan. } \varepsilon - \frac{\varepsilon}{1 + \varepsilon^2}\right) - 2m\right\}.$$

Substituting these values of P and Q$'$ in the equation Pa = Q$'b$, it becomes

$$4\pi a^2\frac{1 + \varepsilon^2}{\varepsilon^3}(\varepsilon - \text{arc tan. } \varepsilon) =$$

$$2\pi b^2\left\{\frac{1 + \varepsilon^2}{\varepsilon^3}\left(\text{arc tan. } \varepsilon - \frac{\varepsilon}{1 + \varepsilon^2}\right) - 2m\right\};$$

whence, putting $a^2(1 + \varepsilon^2)$ instead of b^2, and neglecting the common factors, we get

$$\text{arc tan. } \varepsilon = \frac{3\varepsilon + 2m\varepsilon^3}{3 + \varepsilon^2}\text{..................(1).}$$

In order to discover whether this equation, which is transcendental, has a real root, or how many, we may put

$$\beta = \frac{3\varepsilon + 2m\varepsilon^3}{3 + \varepsilon^2} - \text{arc tan. } \varepsilon\text{............(2),}$$

f and suppose the curve to be described, of which ε is the abscissa, and β the ordinate. This curve will evidently cut the axis at the origin of the co-ordinates; for when $\varepsilon = 0$, we have also $\beta = 0$; but the root $\varepsilon = 0$ has no concern with the question; for the velocity, and consequently ε, is supposed to be a real quantity. By changing the sign of ε, the value of β undergoes no alteration, whence the curve has two equal and similar branches on opposite sides of the origin; we need therefore attend only to the positive values of ε. If then we suppose ε to increase from nothing to infinity, the value of β will begin and end with being positive, whence between these two values of ε the curve will either not cut the axis at all, or cut it an even number of times; or, which is the same thing, the equation has either no roots, or an equal number.

To find the values of ε corresponding to the greatest and least values of β, we must make $d\beta = 0$. Differentiating equation (2), we get, after arranging the terms,

$$\frac{d\beta}{d\varepsilon} = \frac{2\varepsilon^2\{m\varepsilon^4 + (10m - 2)\varepsilon^2 + 9m\}}{(1+\varepsilon^2)(3+\varepsilon^2)^2};$$

whence, making $d\beta = 0$,

$$m\varepsilon^4 + (10m - 2)\varepsilon^2 + 9m = 0 \ldots\ldots\ldots\ldots\ldots (3),$$

the two roots of which are

$$e^2 = 5 - \frac{1}{m} \pm \sqrt{\left(5 - \frac{1}{m}\right) - 9}.$$

Since these are the only roots of equation (3), it follows that there can be only one maximum and one minimum value of the ordinate β on each side of the origin of the abscissa. Hence we infer that the curve intersects the positive abscissa only in two points exclusive of the origin; so that there are two, and only two, real and positive roots of the equation (1). Thus there are two forms of the oblate spheroid, which, for a given velocity of rotation, satisfy the condition of equilibrium; a curious result, which was first made known by Legendre.

The limits within which the roots of equation (1) are possible will be obtained by determining the values of ε and m at the point where the curve touches the axis of the abscissa without cutting it. At this point $\beta = 0$, and $d\beta = 0$. When $d\beta = 0$, equation (3) gives

$$m = \frac{2\varepsilon^2}{\varepsilon^4 + 10\varepsilon^2 + 9} = \frac{2\varepsilon^2}{(1+\varepsilon^2)(9+\varepsilon^2)} \ldots\ldots\ldots (4);$$

substituting this in (2), and making $\beta = 0$, we get, after reduction,

$$\text{arc tan. } \varepsilon = \frac{7\varepsilon^5 + 30\varepsilon^3 + 27\varepsilon}{(3+\varepsilon^2)(1+\varepsilon^2)(9+\varepsilon^2)},$$

or, dividing the terms by $(3 + \varepsilon^2)$,

$$\text{arc tan. } \varepsilon = \frac{7\varepsilon^3 + 9\varepsilon}{(1+\varepsilon^2)(9+\varepsilon^2)};$$

an equation which can have only one positive root besides $\varepsilon = 0$. On solving it by approximation we easily find, on a few trials,

$$\varepsilon = 2{\cdot}5292;$$

whence, from equation (4), the corresponding value of m is

$$m = 0{\cdot}11234.$$

From this we conclude that, when the value of m is smaller than 0·11234, the equation (1) has two unequal positive roots; that when m is equal to this number, the two roots become equal, or the two intersections of the curve with the axis pass into a contact; and that when m is greater than 0·11234, equation (1) has no real roots, or the equilibrium is impossible.

When the eccentricity ε is a very small fraction, as in the case of the earth, the values of the quantities denoted by P and Q may be developed in series proceeding according to the powers of ε, and converging rapidly. Because (see ALGEBRA, sect. XXV. (H 2)

$$\text{arc tan. } \varepsilon = \varepsilon - \frac{\varepsilon^3}{3} + \frac{\varepsilon^5}{5} -, \&c.$$

and because

$$\frac{\varepsilon^2}{1+\varepsilon^5} = \varepsilon - \varepsilon^3 + \varepsilon^5 -, \&c.$$

the preceding expression for P becomes

$$P = 4\pi a \,.\, \frac{1+\varepsilon^2}{\varepsilon^3}\left(\frac{\varepsilon^3}{3} - \frac{\varepsilon}{5} +, \&c.\right);$$

whence, on multiplying, and rejecting all terms involving higher powers of ε than the square,

$$P = 4\pi a\left(\frac{1}{3} + \frac{2}{15}\varepsilon^2\right) = \frac{4\pi a}{3}\left(1 + \frac{2}{5}\varepsilon^2\right).$$

Making the same substitutions in the value of Q, we find

$$Q = 2\pi b\,\frac{1+\varepsilon^2}{\varepsilon^3}\left(\frac{2}{3}\varepsilon^3 - \frac{4}{5}\varepsilon^5 +, \&c.\right),$$

and multiplying as before,

$$Q = 2\pi b\left(\frac{2}{3} - \frac{2}{15}\varepsilon^2\right) = \frac{4\pi b}{3}\left(1 - \frac{1}{5}\varepsilon^2\right).$$

Now, if instead of ε we introduce the ellipticity e, and make $e = \frac{b-a}{a}$, we shall have $b = a(1+e)$. But we have already assumed $b^2 = a^2(1+\varepsilon^2)$; whence $1 + e = \sqrt{1+\varepsilon^2}$; and on rejecting the second and all the higher powers of e (which may be done because e is supposed to be a very small fraction), we have $1 + 2e = 1 + \varepsilon^2$, and consequently $2e = \varepsilon^2$. Substituting this in the above formulas, and observing that $b = a(1+e)$, we get

$$P = \frac{4\pi a}{3}\left(1 + \frac{4}{5}e\right); \quad Q = \frac{4\pi a}{3}\left(1 + \frac{3}{5}e\right);$$

and since $\varphi = 4\pi bm = 4\pi a(1+e)m = 4\pi am$ (for m and e being both very small fractions, their product me may be neglected), we have also

$$Q' = Q - \varphi = \frac{4\pi a}{3}\left(1 + \frac{3}{5}e - 3m\right).$$

Substituting these values of P and Q′ in the equation of equilibrium, $Pa = Q'b = Q'a(1+e)$, there results

$$1 + \frac{4}{5}e = (1+e)\left(1 + \frac{3}{5}e - 3m\right);$$

whence, rejecting terms multiplied by e^2 and em, we find

$$e = \frac{15}{4}m.$$

The ratio of the centrifugal force to gravitation at the equator is $\frac{\varphi}{Q}$, or $\frac{3m}{1 + \frac{3}{5}e - 3m} = 3m$; hence $e = \frac{5}{4} \cdot \frac{\varphi}{Q}$; that is to say, the ellipticity of a homogeneous spheroid revolving about an axis, and whose form does not differ greatly from that of a sphere, is equal to the fraction formed by dividing five times the centrifugal force at the equator by four times the gravitation at the equator. By comparing the length of the arc described by a point on the earth's surface in a second of time, with the descent of falling bodies, Newton found this ratio in the case of the earth to be $\frac{1}{289}$, whence $m = \frac{1}{3 \times 289} = \frac{1}{867}$, and consequently $e = \frac{15}{4} \times \frac{1}{3 \times 289} = \frac{1}{231}$, so that, supposing the earth to be homogeneous, the ratio of its polar to its equatorial axis ought to be 230 to 231 very nearly.

The ellipticity deduced from the actual measurements of degrees, as well as from the variations of gravity indicated by pendulum observations, is considerably less than $\frac{1}{231}$; consequently the earth is not homogeneous.

In what precedes, we have supposed generally $m = \frac{\pi}{t^2}$, and found for the limit which m cannot exceed, $m = 0{\cdot}11234$. Let m' be what m becomes in the case of the earth, and t' be the time (expressed in parts of a mean solar day) in which the earth makes one revolution about its axis; t being the time in which a spheroid of the same mean density as the earth would make a revolution when $m = 0{\cdot}11234$. We have then $m' = \frac{\pi}{t'^2}$, whence $m' : m = t^2 : t'^2$, whence $t = t'\sqrt{\frac{m'}{m}}$. But $t' = 23$ h. 56 m. 4 sec. $= {\cdot}99727$ day; and we have already found $m' = \frac{1}{867}$; therefore $t = {\cdot}99727 \sqrt{\frac{1}{867 \times 0{\cdot}11234}} = 0{\cdot}1009$ day $= 2$ hours 25 minutes 26 seconds. Hence a fluid mass of the same density as the earth could not be in equilibrium with the figure of an ellipsoid of revolution if its time of rotation were less than 2 h. 25 m. 26 sec. If the time of rotation is greater, there are two elliptic spheroids, and not more, which, with the same velocity of rotation, give a figure of equilibrium.

Hitherto we have considered only one of the roots of equation (1), and seen that it gives 230 : 231 as the ratio of the polar to the equatorial axis. Let us now inquire into the value of the other root.

As the value of ε^2 in the former case was very small, it will now be large; we may therefore proceed as follows: The identical equation

$$\text{arc tan. } \varepsilon = \frac{1}{2}\pi - \text{arc tan.} \frac{1}{\varepsilon}$$

gives

$$\text{arc tan. } \varepsilon = \frac{1}{2}\pi - \frac{1}{\varepsilon} + \frac{1}{3\varepsilon^2} - \frac{1}{5\varepsilon^5} +, \&c.$$

whence equation (1) becomes

$$\frac{3\varepsilon + 2m\varepsilon^3}{3\,\varepsilon^2} = \frac{1}{2}\pi - \frac{1}{\varepsilon} + \frac{1}{3\varepsilon^2} - \frac{1}{5\varepsilon^5} +, \&c.$$

Reverting this series, in order to find ε in a series proceeding by the powers of m, we get

$$\varepsilon = \frac{\pi}{4m} - \frac{8}{\pi} + \frac{12m}{\pi}\left(1 - \frac{64}{3\pi^2}\right) +, \&c.$$

or

$$\varepsilon = {\cdot}785398\,\frac{1}{m} - 2{\cdot}546479 - 4{\cdot}436656\,m.$$

Relatively to the earth, it has been seen that $m = \frac{1}{867}$; by substituting which in the above equation, it gives $\varepsilon = 680$ nearly; so that $\sqrt{1 + \varepsilon^2}$, the ratio of the equatorial to the polar axis, is 680 : 1. In this case the spheroid is extremely flattened.

In the preceding propositions it has been demonstrated that a fluid mass of uniform density revolving about a fixed axis will be *in equilibrio*, if its form is that of an oblate spheroid, provided the velocity of rotation does not exceed a certain limit, which has been ascertained. But it has been remarked, that if the same relation exists between the attraction and the centrifugal force as exists in the case of the earth, the ellipticity of such a spheroid would be different from the actual ellipticity of the earth, as determined by observation. It follows that the terrestrial spheroid must be heterogeneous, or of variable density; and this supposition is rendered more probable by what is otherwise known of the nature of the earth. The difficulties of the problem are however greatly increased in the case of a heterogeneous fluid; indeed it is only brought within the power of analysis by assuming that the form of the revolving mass differs very little from that of a sphere, and that it is regularly composed of concentric layers, increasing in density from the surface towards the centre, according to a determinate law. Admitting these assumptions, it may be demonstrated that the oblate spheroid of revolution is in this case also a figure of equilibrium.

The demonstration will be greatly simplified by means of the two following propositions respecting the attraction of homogeneous spheroids of small ellipticity, and which are easily deduced from the properties demonstrated in the article ATTRACTION.

PROP. V.—To find the measure of the attractive forces that urge a particle situated any where within or in the surface of a homogeneous oblate spheroid of revolution, in the directions parallel and perpendicular to the axis, the ellipticity being small.

Let D be the particle, x and y its rectangular co-ordinates (x being taken along the axis, and y perpendicular to the axis, in the meridional plane passing through D); let also X and Y denote the attractive forces soliciting the particle in those directions, and $k =$ the density of the spheroid.

By ATTRACTION (25), $\mathrm{P} : \mathrm{X} = a : x$, and $\mathrm{Q} : \mathrm{Y} = b : y$; therefore $\mathrm{X} = \mathrm{P}\frac{x}{a}$ and $\mathrm{Y} = \mathrm{Q}\frac{y}{b}$. But it has been already shown, that when the elipticity is small,

$$\mathrm{P} = \frac{4\pi}{3}a\left(1 + \frac{4}{5}e\right),\ \mathrm{Q} = \frac{4\pi}{3}a\left(1 + \frac{3}{5}e\right),$$

therefore

$$\mathrm{X} = \frac{4\pi}{3}x\left(1 + \frac{4}{5}e\right);\ \mathrm{Y} = \frac{4\pi}{3}\frac{a}{b}y\left(1 + \frac{3}{5}e\right).$$

Introducing the density k, to which the attraction is directly proportional, and observing that $\frac{a}{b} = \frac{1}{1+e}$, these expressions become

$$\mathrm{X} = \frac{4\pi}{3}kx\left(1 + \frac{4}{5}e\right);\ \mathrm{Y} = \frac{4\pi}{3}ky\left(1 - \frac{2}{5}e\right).$$

PROP. VI.—To find the measure of the forces with which an oblate spheroid, whose ellipticity is small, attracts a particle situated any where without it, in the direction parallel to the axis, and in the direction perpendicular to the axis, the density being uniform.

Let PQ (fig. 14) be the given spheroid, of which the axes are a and b, D the given point without the spheroid, and x' y' the co-ordinates of D. From the two assumed equations $b'^2 - a'^2 = b^2 - a^2$, and $\frac{x'^2}{a'^2} + \frac{y'^2}{b'^2} = 1$, find a' and b', and conceive another spheroid P′Q′ to be described whose polar and equatorial semidiameters are respectively a' and b', whose centre coincides with that of the given spheroid, and which has its equator in the same plane. The surface of this spheroid, in consequence of the equation $\frac{x'^2}{a'^2} + \frac{y'^2}{b'^2} = 1$, will necessarily pass through the point D. Make $x = \frac{ax'}{a'}$, $y = \frac{by'}{b'}$; then, by what is demonstrated in Attraction (26), the point D′, whose co-ordinates are x and y, is in the surface of the given spheroid PQ; and the attraction of the spheroid PQ on a particle at D is to the attraction of the spheroid P′Q′ on the point D′, as $b^2 : b'^2$ in the direction perpendicular to the equator, and as $ab : a'b'$ in the direction perpendicular to a plane passing through the axis. If, therefore, we denote by X and Y the attractions of the given spheroid PQ on D, and by X′ and Y′ those of the spheroid P′Q′ on D′, in the directions of the co-ordinates x and y respectively, we shall have

$$\mathrm{X} : \mathrm{X}' = b^2 : b'^2, \text{ and } \mathrm{Y} : \mathrm{Y}' = ab : a'b',$$

consequently

$$\mathrm{X} = \frac{b^2}{b'^2}\mathrm{X}, \ \mathrm{Y} = \frac{ab}{a'b'}\mathrm{Y}'.$$

But by the last proposition,

$$\mathrm{X}' = \frac{4\pi}{3} kx \left(1 + \frac{4}{5}e'\right), \ \mathrm{Y}' = \frac{4\pi}{3} ky \left(1 - \frac{2}{5}e'\right)$$

(e' being the ellipticity of the spheroid P′Q′p'); therefore

$$\mathrm{X} = \frac{4\pi}{3} \frac{b^2}{b'^2} k \left(1 + \frac{4}{5}e'\right) x, \ \mathrm{Y} = \frac{4\pi}{3} \frac{ab}{a'b'} k \left(1 - \frac{2}{5}e'\right) y;$$

and, on substituting for x and y their values $\frac{a}{a'}x'$ and $\frac{b}{b'}y'$, we have

$$\mathrm{X} = \frac{4\pi}{3} \frac{ab^2}{a'b'^2} k \left(1 + \frac{4}{5}e\right) x'; \ \mathrm{Y} = \frac{4\pi}{3} \frac{ab^2}{a'b'^2} k \left(1 - \frac{2}{5}e\right) y'.$$

We must now eliminate from these equations the quantities a', b', and e', by means of the three equations of condition $\frac{x'^2}{a'^2} + \frac{y'^2}{b'^2} = 1$, $b'^2 - a'^2 = b^2 - a^2$, and $b' = a'(1 + e')$. In order to abridge, let r = CD, the distance of D from the centre of the spheroid, and θ = the angle DCP. We have then $x = r \cos. \theta$, $y = r \sin. \theta$, and the first of the above equations becomes $r^2 (b'^2 \cos.^2 \theta + a'^2 \sin.^2 \theta) = a'^2, b'^2$, which, since $b' = a'(1 + e')$, and consequently $b'^2 = a'^2 (1 + 2e')$, reduces to $r^2 (1 + 2e' \cos.^2 \theta) = a'^2 (1 + 2e')$. On dividing by $1 + 2e'$, and neglecting terms multiplied by e^2, this gives $a'^2 = r^2 (1 - 2e' \sin.^2 \theta)$, and consequently $a'^2 e' = r^2 e'$.

But $b'^2 = a'^2 (1 + 2e')$, therefore $b'^2 - a'^2 = 2a'^2 e'$; and in like manner, $b^2 - a^2 = 2a^2 e$; whence, by reason of $b'^2 - a'^2 = b^2 - a^2$, we have $a'^2 e' = a^2 e$; consequently $a^2 e = r^2 e'$, and $e' = \frac{a^2}{r^2} e$. Substituting this value of e' in the equation $a'^2 = r^2 (1 - 2e' \sin.^2 \theta)$, we get $a'^2 = r^2 - 2a^2 e \sin.^2 \theta$; whence, neglecting terms in e^2, $a' = r - \frac{a^2 e \sin.^2 \theta}{r}$. From the equation $a'^2 = r^2 (1 - 2e' \sin.^2 \theta)$ we also get $b'^2 - a'^2 = b'^2 - r^2 (1 - 2e' \sin.^2 \theta)$; but $b'^2 - a'^2 = 2a'^2 e' = 2a^2 e$; therefore $2a^2 e = b'^2 - r^2 (1 - 2e' \sin.^2 \theta)$, and consequently $b'^2 = r^2 + 2a^2 e \cos.^2 \theta$.

From these values of a' and b'^2 we find, on multiplying and neglecting terms involving the square and higher powers of e, we get $a'b'^2 = r^3 + 2a^2 re \cos.^2 \theta - a^2 re \sin.^2 \theta = r^3 + ra^2 e (2 - 3 \sin.^2 \theta)$. But $b^2 = a^2 (1 + 2e)$, and $ab^2 = a^3 (1 + 2e)$, therefore

$$\frac{ab^2}{a'b'^2}\left(1 + \frac{4}{5}e'\right) = \frac{ab^2}{a'b'^2}\left(1 + \frac{4a^2}{5r^2}e\right)$$

$$= \frac{a^3}{r^3}\left\{1 + 2e - e\frac{3a^2}{5r^2}(2 - 5 \sin.^2 \theta)\right\},$$

and

$$\frac{ab^2}{a'b'^2}\left(1 - \frac{2}{5}e'\right) = \frac{ab^2}{a'b'^2}\left(1 - \frac{2a^2}{5r^2}e\right)$$

$$= \frac{a^3}{r^3}\left\{1 + 2e - e\frac{3a^2}{5r^2}(4 - 5 \sin.^2 \theta)\right\}.$$

Substituting these expressions in the above values of X and Y, writing $r \cos. \theta$ for x', and $r \sin. \theta$ for y', we get

$$\mathrm{X} = \frac{4\pi}{3} k \frac{a^3}{r^2}\left\{1 + 2e - e\frac{3a^2}{5r^2}(2 - 5 \sin.^2 \theta)\right\} \cos. \theta,$$

$$\mathrm{Y} = \frac{4\pi}{3} k \frac{a^2}{r^2}\left\{1 + 2e - e\frac{3a^2}{5r^2}(4 - 5 \sin.^2 \theta)\right\} \sin. \theta.$$

Thus the expression of the force with which a homogeneous spheroid attracts a point placed without it has been found in finite terms. The ingenious process of analysis by which this result, of very great importance in the theory of the figures of the planets, has been obtained, is one of the many discoveries for which mathematical science is indebted to Mr Ivory.

Prop. VII.—To find the measure of the forces with which an oblate spheroid whose ellipticity is small, attracts a particle situated any where on its surface, in the direction parallel to the axis, and in the direction perpendicular to the axis, the density being variable.

In the solution of this problem we suppose the spheroid to be composed of infinitely thin concentric layers, bounded by spheroidal surfaces of different ellipticities, and that the density is uniform for a single layer, but variable from one layer to another.

Let P′Q′ (fig. 15) be the given spheroid, a', b' its polar and equatorial radii, and D the attracted point. Let D be any point within the spheroid P′Q′, and PQD′ be a spheroidal surface at every point of which the density is the same, a, b its polar and equatorial radii, and e its ellipticity. Also let p, q be another spheroidal surface indefinitely near PQ, of which the polar radius C$p = a + da$, the equatorial C$q = b + db$, and the ellipticity $= e + de$. Between the two surfaces PQ and pq the density k may be supposed constant.

In order to find the attraction of the whole spheroid on D, we must first find expressions in terms of a for the forces with which D is attracted by the elementary layer PQpq; the integration of these expressions from $a = 0$ to $a = a'$ will give the attractions of the spheroid.

Conceive for a moment the density of the spheroid CPQ to be uniform and $= k$. The forces X and Y with which this spheroid attracts D are given by the last proposition, and the forces with which Cpq attracts D will be found by substituting $a + da$ for a, and $e + de$ for e in the same expressions for X and Y. Now, as the ellipticity varies from C to P′, e may be regarded as a function of a; its variation is consequently included in the variation of a, and the attractions of the spheroid Cpq hence become

$$\mathrm{X} + \frac{d\mathrm{X}}{da} da, \ \mathrm{Y} + \frac{d\mathrm{Y}}{da} da.$$

The difference between the attractions of the spheroids Cpq and CPQ is the attraction of the layer PQqp, which is therefore $\frac{d\mathrm{X}}{da} da$, and $\frac{d\mathrm{Y}}{da} da$. Hence, if we represent the attractions of the whole heterogeneous spheroid CP′Q′ by X′ and Y′, we shall have

$$\mathrm{X}' = \int \frac{d\mathrm{X}}{da} da, \ \mathrm{Y}' = \int \frac{d\mathrm{Y}}{da} da,$$

which integrals must be taken from $a = 0$ to $a = a'$, the density k, which enters as a factor into X and Y, being regarded as a function of a.

Let us first consider the force X′. By last proposition we have

$$\mathrm{X} = \frac{4\pi}{3} k \frac{a^3}{r^2}\left\{1 + 2e - e\frac{3a^2}{5r^2}(2 - 5 \sin.^2 \theta)\right\} \cos. \theta,$$

Figure of the Earth.

whence

$$\frac{dX}{da}da=\frac{4\pi k}{3\,r^2}\left\{d(\overline{1+2e}.a^3)-\frac{3}{5r^2}(2-5\sin.^2\theta)d(a^5e)\right\}\cos.\theta.$$

Integrating, and regarding k as variable, and a function of a, and going through the same process with respect to Y, we get for the attractions of the spheroid CP′Q′ in the directions respectively parallel and perpendicular to the axis,

$$X'=\frac{4\pi}{3}\left\{\frac{1}{r^2}\int kd(\overline{1+2e}.a^3)-\frac{3(2-5\sin.^2\theta)}{5r^4}\int kd(a^5e)\right\}\cos.\theta,$$

$$Y'=\frac{4\pi}{3}\left\{\frac{1}{r^2}\int kd(\overline{1+2e}.a^3)-\frac{3(4-5\sin.^2\theta)}{5r^4}\int kd(a^5e)\right\}\sin.\theta.$$

Prop. VIII.—To find the measure of the forces with which a heterogeneous layer, included between two level surfaces, attracts a particle situated anywhere within it.

Let D′ (fig. 15) be the given particle situated within the spheroidal layer PQQ′P′, x' and y' the co-ordinates of D′, a = polar semiaxis, and e = eccentricity of the inner surface PQ passing through D′, a' = polar semiaxis of the exterior surface P′Q′, and k = density at the interior surface.

Suppose the interior of the spheroid PQ to be filled with matter of uniform density k, then by Proposition V., the attractions of that spheroid on D′ are

$$X=\frac{4\pi}{3}k\left(1+\frac{4}{5}e\right)x',\ Y=\frac{4\pi}{3}k\left(1-\frac{2}{5}e\right)y';$$

or, changing x' into r cos. θ, and y' into r sin. θ,

$$X=\frac{4\pi}{3}r'k\left(1+\frac{4}{5}e\right)\cos.\theta,\ Y=\frac{4\pi}{3}rk\left(1-\frac{2}{5}e\right)\sin.\theta.$$

Now the attraction of another similar spheroid Cpq, whose polar semiaxis is $a+da$, will be found by substituting $a+da$ for a and $e+de$ for e in the above expressions; and the attraction of the elementary layer PQpq on D will be the difference of these attractions. But

$$\frac{dX}{da}da=\frac{4\pi}{3}\cdot\frac{4}{5}rkde\cos.\theta,$$

$$\frac{dY}{da}da=-\frac{4\pi}{3}\cdot\frac{2}{5}rkde\sin.\theta,$$

e being regarded as a function of a. The integral of these expressions will give the attraction of the layer PQqp on D′; but as this attraction diminishes while a increases, if we take A to represent what $\int kde$ becomes when a becomes a', and denote by X″ and Y″ the attractions of the whole layer PQQ′P′, we shall have

$$X''=\frac{4\pi}{3}\cdot\frac{4}{5}r\left(A-\int kde\right)\cos.\theta,$$

$$Y''=-\frac{4\pi}{3}\cdot\frac{2}{5}r\left(A-\int kde\right)\sin.\theta.$$

Prop. IX.—To find the attraction of a heterogeneous spheroid on a point within it.

Let D′ (fig. 14) be the given point, and CP′Q′ the given spheroid, r cos. θ and r sin. θ the co-ordinates of D′, a', and e', the polar semiaxis and ellipticity of the given spheroid CP′Q′, and a and e those of the spheroidal surface passing through D′ and all the points of equal density.

The whole force urging D′ may be conceived as made up of two parts; that arising from the spheroid CPQ, the surface of which passes through D, and that of the spheroidal shell PQQ′P′. The first of these forces is given by the expressions represented by X′ and Y′ in Prop. VII. and the second by the expressions represented by X″ and Y″ in Prop. VIII. Therefore, if we denote by X‴ and Y‴ the attractions of the whole spheroid on the particle D′, in the direction parallel to the axis, and in the direction perpendicular to the axis, we shall have

$$X'''=X'+X'',\quad Y'''=Y'+Y'';$$

and if the spheroid revolves about its polar axis, Y‴ must be diminished by the amount of the centrifugal force = $\frac{4\pi}{3}\cdot\frac{3\pi}{t^2}r\sin.\theta$; therefore the attractions of the given spheroid on the point D′ are

$$X'''=X'+X'',$$

$$Y'''=Y'+Y''-\frac{4\pi}{3}\cdot\frac{3\pi}{t^2}r\sin.\theta.$$

Prop. X.—To find the ratio of the ellipticity to the density of any level surface, when the component of all the forces urging any point on the surface is perpendicular to the surface.

The forces urging the particle D′ (fig. 14) being X‴ and Y‴, in order that their resultant may be perpendicular to the surface, we must have

$$X''':Y'''=ME:ED\ \text{(fig. 10)}.$$

But ME (the subnormal) $=\frac{b^2}{a^2}x'=(1+2e)x'$, and ED $=y'$; therefore X‴ : Y‴ $=(1+2e)x':y'$, whence, substituting r cos. θ for x' and r sin. θ for y', $\frac{X'''}{\cos.\theta}-\frac{Y'''}{\sin.\theta}(1+2e)=0.$

Now, if we substitute for X‴ in this equation the values of X′ and X″ given by Propositions VII. and VIII., and for Y‴ the values of Y′ and Y″ multiplied by $(1+2e)$, and neglect terms involving e^2, we shall find, on changing the signs and having regard to the centrifugal force,

$$\frac{2e}{r^2}\int kd(\overline{1+2e}.a^3)-\frac{6}{5r^4}\int kd(a^5e)-\frac{6}{5}r\left(A-\int kde\right)-\frac{3\pi r}{t^2}=0.$$

Dividing by $2r$, and substituting a for r (which may be done without sensible error, because all the terms of the equation are small, and because r^2 differs from a^2 only by a quantity depending on the ellipticity e), we shall find

$$\frac{e}{a^3}\int kd(\overline{1+2e}.a^3)-\frac{3}{5a^5}\int kd(a^5e)-\frac{3}{5}\left(A-\int kde\right)-\frac{3\pi}{2t^2}=0.$$

From this we infer that if k and e have the relation to each other indicated by this equation, and that e is very small from $a=0$ to $a=a'$, each of the level surfaces will be intersected at every point by the resultant of the attractive forces under an angle which will differ from a right angle only by an infinitesimal of the second order, supposing the centrifugal force to be very small in comparison of gravity. Hence, neglecting quantities of the second order, the elliptical spheroid (supposing the equation possible) is a figure of equilibrium.

In order to discover whether the equation which has now been obtained is possible, it must be differentiated twice in order to eliminate $\int kd(a^5e)$ and $\int kde$, both of which contain the ellipticity e. Observing that as the first term is multiplied by e, we may suppose, without sensible error, $\frac{e}{a^3}\int kd(\overline{1+2e}.a^3)=\frac{e}{a^3}\int kd(a^3)=\frac{3e}{a^3}\int ka^2da$, and the first differentiation gives, on multiplying by a^6,

$$\frac{de}{da}a^3\int ka^2da-3a^2e\int ka^2da+\int kd(a^5e)=0.$$

Differentiating again, and considering da as constant, we shall find, after reduction,

$$\frac{d^2e}{da^2}+\frac{2ka^2}{\int ka^2da}\cdot\frac{de}{da}+\left(\frac{2ka}{\int ka^2da}-\frac{6}{a^2}\right)e=0.$$

This is the equation given by Clairaut (*Figure de la Terre*, p. 276). It can be integrated by the usual methods when k is expressed in terms of a; consequently the equilibrium is always possible if the density is a function of the distance from the centre. The integration being performed, an equation will result between the densities and ellipticities of the different spheroidal layers, by means of which, when one of these elements is supposed to be given, the other can be determined.

Prop. XI.—To find the whole force urging a particle situated at any point on the surface of a heterogeneous spheroid revolving about its shorter axis.

By Prop. VII. the force urging the particle in the direction of the axis is X′, and in the direction perpendicular to the axis Y′; but in consequence of the centrifugal force, the latter becomes $Y' - \varphi$, therefore the whole force urging D in the direction of the normal

$$=\sqrt{X'^2+(Y'-\varphi)^2}.$$

Neglecting the terms which involve e^2 and $e\varphi$ (φ being small as well as e), and putting $\int kd\,(\overline{1+2e\cdot a^3}) = M$, and $\int kd\,(a^5 e) = N$, and substituting $\frac{4\pi^2}{t^2} r \sin.\theta$ for φ, we get

$$X'^2 = \left(\frac{4\pi}{3r^2}\right)^2 \left\{ M^2 \cos.^2\theta - \frac{6(2-5\sin.^2\theta)}{5r^2} M N \cos.^2\theta \right\},$$

$$(Y'-\varphi)^2 = \left(\frac{4\pi}{3r^2}\right)^2 \left\{ M^2 \sin.^2\theta - \frac{6(4-5\sin.^2\theta)}{5r^2} MN \sin.^2\theta \right.$$
$$\left. \frac{6M\pi r^3 \sin.^2\theta}{t^2} \right\};$$

whence, putting $X^2 + (Y-\varphi)^2 = U^2$, there results

$$U^2 = \left(\frac{4\pi}{3r^2}\right)^2 \left\{ M^2 - \frac{6(2-3\sin.^2\theta)}{5r^2} MN \right.$$
$$\left. - \frac{6M\pi r^3 \sin.^2\theta}{t^2} \right\},$$

and extracting the square root,

$$U = \frac{4\pi}{3} \left\{ \frac{M}{r^2} - \frac{3(2-3\sin.^2\theta)}{5r^4} N - \frac{3\pi r \sin.^2\theta}{t^2} \right\}.$$

But the equation of the ellipse gives

$$r^2 \cos.^2\theta + \frac{r^2 \sin.^2\theta}{1+2e} = a^2;$$

whence we deduce $r^2 = a^2(1+2e\sin.^2\theta)$; therefore, substituting and dividing, and neglecting terms in Ne and $e\varphi$,

$$U = \frac{4\pi}{3} \left\{ \frac{M}{a^2}(I - 2e\sin.^2\theta) - \frac{3}{5}\cdot\frac{(2-3)\sin.^2\theta}{a^4} N \right.$$
$$\left. - \frac{3\pi^2 a \sin.^2\theta}{t^2} \right\}$$

Let the centrifugal force at the equator $= m \times$ gravity; then, if m is a very small fraction (as in the case of the earth, where $m = \frac{1}{289}$), terms involving the product me may be neglected, and the last equation, multiplied by m, will become

$$mU = \frac{4\pi}{3}\cdot\frac{M}{a^2} m;$$

but the centrifugal force at the equator $= \frac{4\pi^2}{t^2} a(1+e)$, which does not differ sensibly from $\frac{4\pi^2}{t^2} a$; therefore $\frac{4\pi^2}{t^2} a = \frac{4\pi}{3} \frac{M}{a^2} m$, or $\frac{3\pi}{t^2} = \frac{Mm}{a^3}$. Now, at the surface the equation of equilibrium in Prop. X. becomes

$$\frac{e}{a^3} M - \frac{3}{5a^5} N - \frac{3\pi}{2t^2} = 0,$$

therefore

$$\frac{e}{a^3} M - \frac{3}{5a^5} N - \frac{Mm}{2a^3} = 0,$$

whence

$$\frac{3N}{5a^4} = \frac{M}{a^2}\left(e - \frac{m}{2}\right).$$

Substituting these values of $\frac{3\pi}{t^2}$ and $\frac{3N}{5a^4}$ in the above value of U, we get, after reduction,

$$U = \frac{4\pi}{3}\cdot\frac{M}{a^2}\left\{1 - 2e + m - \left(\frac{5}{2}m - e\right)\sin.^2\theta\right\}.$$

At the equator $\sin.\theta = 1$, and this equation becomes

$$Q = \frac{4\pi}{3}\cdot\frac{M}{a^2}\left\{1 - e - \frac{3}{2}m\right\};$$

and at the pole, where $\sin.\theta = 0$, it gives

$$P = \frac{4\pi}{3}\cdot\frac{M}{a^2}\left\{1 - 2e + m\right\};$$

consequently the difference between the force of gravity at the pole and that of gravitation at the equator is $\frac{4\pi}{3}\cdot\frac{M}{a^2}\left(\frac{5m}{2} - e\right)$. Dividing this by the polar gravity P, we get for the quotient $\frac{5m}{2} - e$, which, therefore, expresses the ratio of the excess of the polar gravity above the gravitation at the equator to the gravity at the pole. Let this ratio $= n$, we have then

$$n = \frac{5}{2}m - e;$$

a very remarkable relation between the gravity and ellipticity, which was discovered by Clairaut, and is generally called *Clairaut's theorem.*

If we substitute $1 - \cos.^2\theta$ for $\sin.^2\theta$ in the equation

$$U = \frac{4\pi}{3}\cdot\frac{M}{a^2}\left\{1 - 2e + m - \left(\frac{5}{2}m - e\right)\sin.^2\theta\right\},$$

we get

$$U = \frac{4\pi}{3}\cdot\frac{M}{a^2}\left\{1 - e - \frac{3}{2}m + \left(\frac{5}{2}m - e\right)\cos.^2\theta\right\};$$

or, neglecting quantities of the order me,

$$U = \frac{4\pi}{3}\cdot\frac{M}{a^2}\left(1 - e - \frac{3}{2}m\right)\left\{1 + \left(\frac{5}{2}m - e\right)\cos.^2\theta\right\};$$

whence we have $U = Q(1 + n\cos.^2\theta)$. Now in this equation the angle θ may be taken for the complement of the latitude, from which indeed it differs only by a quantity of the second order, and the equation then becomes $U = Q(1 + n\sin.^2 l)$; whence we infer that, on going from the equator towards the pole, the increase of gravity is proportional to the square of the sine of the latitude.

Let p be the length of the seconds pendulum at the equator, p' its length at any latitude l, and U the intensity of the gravitating force at the same latitude l. When the time of oscillation is constant, the length of the pendulum is directly proportional to the intensity of gravity; therefore $p' : p = U : Q$, and consequently

$$\frac{p'-p}{p} = \frac{U-Q}{Q}.\quad \text{But } U = Q(1 + n\sin.^2 l),$$

therefore, $\frac{p'-p}{p} = n\sin.^2 l = \left(\frac{5m}{2} - e\right)\sin.^2 l.$

At the pole $\sin.l = 1$, and $\frac{p'-p}{p} = \frac{5m}{2} - e$; therefore, since $e = \frac{b-a}{a}$, $\frac{p'-p}{p} + \frac{b-a}{a} = \frac{5m}{2}$.

Now it has been shown that in the case of a homogeneous spheroid the ellipticity is $\frac{5\,m}{4}$; hence we have this theorem:

In the case of a heterogeneous spheroid, the excess of the length of the pendulum at the pole above its length at the equator divided by its length at the equator, and the excess of the axis of the equator above the polar axis divided by the polar axis, form two fractions, of which the sum is constant, and equal to twice the ellipticity the spheroid would have if homogeneous.

SECTION IV.

ON THE FIGURE OF THE EARTH AS DETERMINED BY OBSERVATIONS OF THE PENDULUM.

As the various methods of determining the length of a pendulum which makes a given number of vibrations in a mean solar day, and the corrections that are required to reduce the observations to the same circumstances in respect of altitude, temperature, barometric pressure, &c. form the subject of a separate article, we shall here limit ourselves to a brief abstract of the results of some of the latest and best observations.

The ellipticity of the earth is deduced from the observed number of vibrations made by an invariable pendulum of a given length at different latitudes, by means of the theorem of Clairaut. Let $N =$ the number of oscillations made by a pendulum at the equator in a mean solar day, $N' =$ the number of oscillations made by the same pendulum at the latitude l; then Q representing, as before, the gravitation at the equator, and U the gravitation at latitude l, we have, by the last proposition in the preceding section,

$$U = Q\,(1 + n \sin.^2 l).$$

But by the property of the invariable pendulum, the square of the number of vibrations is directly proportioned to the force of gravitation; therefore $U : Q = N'^2 : N^2$, whence $N'^2 = N^2\,(1 + n \sin.^2 l)$.

In this equation $n = \frac{5}{2}\,m - e = \frac{5}{2 \times 289} - e$; therefore, as N'^2 is given by observation at any station, we can, by combining the results at two different latitudes, determine N and n, and consequently e. The pendulum gives no information respecting the magnitude of the earth.

Instead of N and N′, we might substitute in the above equation the lengths of the seconds pendulum at the equator, and the latitude l (the length of the seconds pendulum being also directly proportional to the intensity of gravity); but as the invariable pendulum is now almost universally employed for the measurement of the variations of gravity, the formula under the above form is more immediately applicable to the results of observation. The absolute length of the pendulum (which is not very easily determined) has no concern with the present question.

For the purpose of exhibiting the variations of gravity, we shall confine our attention to the results that have been found from observations with the invariable pendulum. The results given by pendulums of a different kind are probably not less exact, but they are not directly comparable, on account of the great uncertainty that remains respecting the correction that ought to be applied for the buoyancy of the atmosphere.

In the seventh volume of the *Memoirs of the Royal Astronomical Society*, Mr Baily has given the results of fourteen different sets of observations with invariable pendulums. They are as follows:

1. The observations of Captain Kater at different stations in Great Britain. These are detailed in the *Philosophical Transactions* for the year 1819.

2. Those of Mr Goldingham at London and Madras, and of Mr Lawrence and Mr Robinson with the same pendulum at the small island of Pulo Guansah Lout, on the western coast of Sumatra, and almost immediately under the equator. (*Phil. Trans.* 1822.)

3. Those of Captain Hall at the Galapagos Islands, San Blas, Rio Janeiro, and London. (*Phil. Trans.* 1823.)

4. Those of Sir Thomas Brisbane at London and Paramatta. (*Phil. Trans.* 1823.)

5. Those of Captain Sabine in various parts of the Atlantic Ocean and the North Sea, in the years 1822-4. (Sabine's *Account of Experiments*, &c. 1825.)

6. Those of Captain Foster at Greenwich, London, and Port Bowen. (*Phil. Trans.* 1826.)

7. Those of Mr Fallows at the Cape of Good Hope. The same pendulum was swung in London previous to its departure.

8, 9, 10. Those of Captain Sabine for the purpose of determining the difference in the number of oscillations at London and Paris (*Phil. Trans.* 1828), London and Greenwich (*Phil. Trans.* 1829), and at Greenwich, London, and Altona (*Ibid.* 1829 and 1830).

11. Those of Captain Freycinet, who commanded an expedition fitted out by the French government in 1817, for the purpose of making scientific observations in a voyage round the world. The stations at which the experiments were made were the island of Rawak (near the coast of Guinea), Guam (one of the Ladrones), the Isle of France, Mowi (one of the Sandwich Islands), Rio Janeiro, Port Jackson, Cape of Good Hope, Paris, and the Falkland Islands. (*Voyage autour du Monde, par M. Freycinet.*)

12. Those of Captain Duperrey, who commanded another French expedition. The stations were, island of Ascension, Isle of France, Port Jackson, Toulon, Paris, and the Falkland Islands. (*Connoissance des Tems* for 1830.)

13. Those of Captain Leutke, a Russian officer, under whose orders a ship of war was dispatched to the South Seas, for the purpose, among other things, of swinging the pendulum at various places. The stations at which experiments were made were Ualan (one of the Caroline Isles), Guam, St Helena, Bonin Island (off the south-east coast of Japan), Valparaiso, Greenwich, Petropaulouski, Sitka (off the north-west coast of America), and Petersburg. (Mr Baily's Report in the *Memoirs of the Royal Astronomical Society*, vol. vii.)

14. Those of Captain Foster, in his last voyage, which commenced in 1828, and which form perhaps the most valuable series of the whole. The observations were made at fourteen different stations, principally in the southern hemisphere, from the equator to the latitude of 63°. Captain Foster carried out with him four pendulums, two of brass, one of iron, and one of copper, and at seven of the stations all four were swung. The details are published at full length in the volume of the *Astronomical Society's Memoirs* to which we have already referred, with an excellent Report by Mr Baily.

The results of all these observations are contained in the following table, in which the observed number of vibrations at each station is corrected, for any deviation from the standard temperature of 62°, or from the true correction for the buoyancy of the atmosphere, and afterwards reduced to a comparison with Captain Foster's mean pendulum, assumed as making 86,400 vibrations in a mean solar day at London.

No.	Station.	Latitude.	Vibrations. Observed.	Vibrations. Computed.	Difference.	Observer.

Taking the mean results of the observed vibrations given in col. 4 of the above table, and forming with each of them the equation of condition $N'^2 = N^2 (1 + n \sin.^2 l)$, seventy-nine equations are formed, from which, on deducing the values of N^2 and n by the method of least squares, Mr Baily obtained the following results:

$$N^2 = 7441625711$$
$$n = \cdot 00514491$$
$$e = \frac{1}{285 \cdot 26}.$$

By means of these values of N^2 and n, the number of vibrations made by a pendulum which beats seconds at London, at any latitude l, supposing the earth to be a regular spheroid, is given by the formula

$$N' = 86246 \cdot 8 (1 + \cdot 00514491 \sin.^2 l)^{\frac{1}{2}};$$

and from this the results given in col. 5 of the table have been computed.

Although the differences between the observed and computed vibrations are in some instances considerable, the observations are on the whole well represented by supposing the ellipticity $= \frac{1}{285 \cdot 26}$. To be satisfied of this, it will be sufficient to remark, that as the differences in the table present twenty-four alternations of sign, the curve which represents all the observations intersects the meridian having that ellipticity no less than twenty-four times along an arc of 152° (from Spitzbergen to South Shetland), or, on an average, once for every 6¼ degrees; and (with the exception of the island of Bonin) the deviations on the opposite sides are nearly equal.

If, instead of seeking an ellipticity by the *fusion* (if we may so speak) and agglomeration of all the observations by the method of least squares, we consider the results of the different voyagers separately, we shall find marked differences among them. Taken by themselves, Captain Sabine's observations give $e = \frac{1}{288 \cdot 4}$; Captain Foster's, $e = \frac{1}{289 \cdot 5}$; Duperrey's, $e = \frac{1}{266 \cdot 4}$; Freycinet's, $e = \frac{1}{267 \cdot 6}$; and Leutke's, $e = \frac{1}{267 \cdot 7}$. The singular agreement of the results of the foreign voyagers with each other, and their difference from those of Captains Sabine and Foster, which also agree well with each other, have not been satisfactorily explained.

In one of the numbers of the *Annales des Sciences d'Observation* (tome i. No. 3), M. Saigey has computed the ellipticity from fifty-one different observations, combined by the method of least squares. Captain Foster's observations are of course not included in the table; but it contains those of Biot, made with a variable pendulum at different stations along the French and British arcs of meridian, and more recently in Italy and the Lipari Islands. The result gives $e = \frac{1}{286 \cdot 5}$.

The differences between the observed and computed values are, in many instances at least, too great to be ascribed entirely to errors of observation. They must, therefore, be occasioned by real differences in the intensity of gravity, arising either from variations in the density of the materials which compose the exterior crust of the earth, or from local deviations of its form from that of the regular spheroid. On attending to the preceding table, it will be perceived that the differences are generally in excess where the station is on small islands, and especially if situated at a great distance from the main land. From this it may be inferred, that such islands are composed of denser materials than the general crust of the earth; but it is not improbable that part of this effect may be occasioned by a difference of the level of the surface of the ocean. On the shores of elevated continents, the direction of gravity is altered by the action of the high land; and the surface of the water, which is perpendicular to gravity, deviates from the regular curvature, and becomes elevated above the general level of the ocean. Hence the apparent elevation is less than the real elevation of the station, and the observed intensity of gravity is consequently less than it was calculated to be. How far the disturbing influence of this cause may affect the results, will be better understood when we shall be furnished with numerous pendulum observations, made in the interior of the large continents, and at a great distance from the sea.

All the pendulum experiments agree in giving a greater ellipticity to the earth than that which is deduced from the comparison of arcs of meridian. To what cause this discrepancy is to be assigned is by no means apparent. The geological character of the country in the immediate neighbourhood of the station probably exerts a considerable influence in accelerating or retarding the pendulum; but the experiments have now been made at so many points, that we might expect to find the effects of local irregularities almost entirely eliminated, and a much nearer agreement between the results of the two methods of investigation than actually exists. We can, however, have no difficulty in giving the preference to the results of the geodetic measures.

It was mentioned in the first section of this article that the ellipticity of the earth may be deduced from certain inequalities in the motions of the moon, to which it gives rise; but this part of the subject belongs to the theory of the lunar perturbations. The ellipticity so deduced is about $\frac{1}{306}$, which agrees well with that given by the meridional arcs; and the result has the advantage of being entirely independent of local disturbance.

One conclusion cannot fail to be drawn from the results of this enquiry. However irregular the surface of the earth may be in its details, its general form agrees so nearly with the figure of hydrostatic equilibrium, that the agreement cannot be regarded as fortuitous or accidental. The regular increase of gravity from the equator to the poles, indicated by the pendulum experiments, also proves that it is symmetrically constituted, or that the materials in its interior are disposed about the centre of gravity in regular elliptical strata, and arranged according to the order of density. The earth must therefore have taken its present form while its particles were at liberty to arrange themselves in obedience to the forces arising from their mutual attractions and from the rotation; in other words, it must have existed at some period of time in a state of fluidity. This inference, which so many geological facts tend to confirm, may be extended to all the other planets. (s.)

FILAMENT, in *Anatomy* and *Natural History*, a term used in the same sense with fibre, and signifying those fine threads of which the flesh, nerves, skin, plants, roots, &c. are composed.

Vegetable FILAMENTS form a substance of great use in the arts and manufactures; furnishing thread, cloth, cordage, and the like. For these purposes the filamentous parts of the *Cannabis* and *Linum*, or hemp and flax, are commonly used amongst us. But different vegetables have been employed in different countries for the same uses. Putrefaction destroys the pulpy or fleshy matter, and leaves the tough filaments entire. By putrefying the leaf of a plant in water, we obtain the fine flexible fibres which constitute the basis of the ribs and minute veins, and form as it were a skeleton of the leaf. The Sieur de Flacourt, in his history of Madagascar, relates that different kinds of cloth are prepared in that island from the filaments of the bark of certain trees boiled in a strong lye; that some of these cloths are very fine, and approach to the softness of silk, but in durability fall short of cotton; that others are coarser and stronger, and last thrice as long as cotton; and that of these the sails and cordage of his vessel were made.

FILANDERS, in falconry, a disease in hawks, and some other birds, consisting of filaments or strings of blood coagulated; and occasioned by a violent rupture of a vein, by which the blood extravasated hardens into these figures, and incommodes the reins, hips, and other parts.

FILANDERS are also worms as small as thread, and about an inch long, which lie wrapt up in a thin skin or net, near the reins of a hawk, apart from either gut or gorge.

FILANGIERI, GAETAN, celebrated for his valuable works on political economy and legislation, was born at Naples on the 18th of August 1752. He was the third son of Cesar prince of Araniello, by Marianne Montalto, daughter of the Duke of Fragnito. His family was ancient, and rose to distinction at the first establishment of the Neapolitan monarchy. Angerio, its founder, was the son of one of those brave Normans who landed in Italy about the beginning of the eleventh century, and accompanying Count Roger in all his military expeditions, received from him ample domains as the reward of his exploits. His descendants were allowed to take the honourable title of *Filii Angerii*, and hence the name Filangieri. Gaetan from his infancy was destined for the profession of arms; when he was seven years of age he was enrolled in one of the royal regiments, and he commenced actual service at the age of fourteen. His education was at first neglected, from a misconception of his character, which was supposed to be averse to all literary or speculative pursuits. The injudicious methods adopted at that time in the teaching of Latin had, it seems, disgusted him, and alienated his mind from the study of this language; and hence an impression had been hastily taken up of his general unfitness for all literary exercises. A lucky accident, however, not only removed this apprehension, but showed that his former impatience of the modes of tuition then in use arose from the clearness and vigour of his judgment. It happened that his brother's preceptor had one day mistaken the solution of some geometrical problem. Gaetan immediately perceived the source of this error, which he demonstrated to the master. This incident, apparently trivial, determined his future destiny. Encouraged by his success, he quitted the military service, and determined to follow his natural taste for science and philosophy. So diligent was he in repairing the defects of his education, that at twenty years of age he had acquired a knowledge of Greek and Latin, of ancient and modern history, of the great principles both of civil and of public law, and was besides well initiated in mathematical science. Although his genius inclined him solely to the study of legislation and policy, he sacrificed his views to the wishes of his friends, and entered on the profession of the law, which was then the certain road both to honour and fortune. His eloquence and his extensive knowledge soon obtained him success; and, about this period, a circumstance happened which greatly conduced to his celebrity. Enormous abuses prevailed in the administration of justice at Naples, arising from the uncertainty of the law, which occasioned constant misconceptions, and almost always led to arbitrary judgments. By a wise ordinance of the king, passed in the year 1774, at the suggestion of the minister Tanucci, those abuses were reformed; the law was restored to its proper authority; its judgments were freed from the control of precedents; and the judges were ordained in every case to publish the grounds of their decisions. Although this reform was generally applauded, it excited the murmurs of the bar. Filangieri now became the advocate of the court, and published a defence of the royal decree, founded upon the most enlarged views of equity and reason. The extensive knowledge and matured judgment displayed in this performance attracted the attention of the ministers, and Filangieri was encouraged to pursue the course in which he had already acquired so much distinction. Through the influence of his uncle, the Archbishop of Palermo, he was in 1777 placed in an honourable office at court; and almost at the same time he was named officer of the royal corps of marine volunteers, who were more particularly attached to the king's person. But his abode at court neither broke in upon his regular habits of life, nor interrupted the course of his studies; nor did he allow it to interfere with the composition of the great work on legislation and government in which he was engaged, and to which for several years past he had devoted all his inquiries. About the commencement of the eighteenth century a great school of philosophy had been formed at Naples, in which the principles of the civil law, of the law of nations, and of legislation, were established on the solid and comprehensive basis of general utility. From this school numerous works of celebrity have proceeded; amongst others, the great work of Beccaria, which, though confined to one branch of legislation, contains principles which are of universal application. There was still wanting, however, a general treatise on legislation, for the purpose of examining the science in all its relations, and of laying down some common and universal principles of equity and expediency as its only true basis; and it was to this important undertaking that Filangieri's philosophical mind was now directed. His subject he proposed to divide into seven books. The first, in which he demonstrates the general rules of legislation, and the second, which treats on political laws, and on those laws also which are connected with the general structure of society, appeared at Naples in 1780; and such was its popularity, that not only in Italy, but throughout Europe at large, the author was ranked among the most celebrated writers on public law. According to his theory, the goodness of laws is either absolute or relative. It is absolute when they are agreeable to those great and universal principles of equity and expediency which are obligatory on man under every diversity of country, climate, government, or manners; it is relative, according as the laws agree with the nature of the government, with the genius and character of the people, with the climate, with the fertility or sterility of the soil, with the physical circumstances of the country, with the religion of the inhabitants, and with the degree of civilization to which they have advanced. In his second book, which treats of political laws, and of those laws also which are connected with the general economy of society, he examines two points; namely, the state of population and of wealth. With respect to the first point, the great question which he considers is, whether Europe is as populous as it might be? This question he resolves in the

Filangieri.

negative, and he proceeds to explain the causes of this deficient population. According to his hypothesis, the state of agriculture affords in every country the surest evidence as to the state of the population; but the backwardness of agriculture in most parts of Europe sufficiently indicates that the population is deficient; therefore he infers the defective state of European legislation on these two capital points. The great obstacles to the improvement of agriculture, and, consequently, to the increase of population, he considers to be, 1*st*, the small number of proprietors, and the great number of non-proprictors; 2*dly*, too many large, and too few small properties; 3*dly*, the exorbitant and inalienable possessions of the church in several states; 4*thly*, the excess of the public imposts, and the violent modes of levying them; 5*thly*, to these he adds other causes of less importance, such as the state of most of the regular troops of the European states; also public corruption, and the dissoluteness of private morals. The progress of agriculture, the great source of wealth as well as of population, may also be obstructed by a bad political administration, by bad laws, or by those causes which occasion a great influx of inhabitants to the respective capitals of the different states. It belongs to a pure system of legislation to remove some of those obstacles, and to counterbalance such others as are inevitable, by suitable encouragements. Having discussed those momentous questions, he next enters into a comprehensive survey of the other sources of riches, namely, arts, manufactures, and commerce, and points out how these may be obstructed by a faulty legislation, and, at the same time, the means by which such obstructious may be removed. In order fully to comprehend the merits of these performances, we must consider that all the faults which the author reprehends were committed by his own government; a circumstance which imposed on him the delicate task of stating obnoxious truths with freedom and boldness, and, at the same time, without giving unnecessary offence. So well, however, did he appreciate the views of those whom it was his wish to enlighten, that he was immediately promoted by the king to a commandery in the royal order of Constantine. In 1783 he married a Hungarian lady of noble birth, who was entrusted with the education of the second daughter of the king, and who to outward attractions united the gift of a sound judgment and an agreeable disposition. That he might the more freely enjoy domestic happiness, and, at the same time, have leisure for the composition of his work, on which he became every day more intent, he resigned, with the consent of the king, all his military employments and his office at court, and retired to a country-seat about twenty miles from Naples. In the same year he published his third book, relating entirely to the principles of criminal jurisprudence. In these discussions he maintains the same tone of decision and independence as before. Abuses are freely pointed out, and the defects of the penal code, and the forms of criminal procedure, are fairly exposed. In thus pointing out those defects in the domestic administration of his government, Filangieri excited the hatred of an interested and powerful class; and a proposition which he made in his third book, for the reformation of abuses in the Roman Catholic church, drew down upon his work the censure of some of the ecclesiastical tribunals. In 1785, however, he published the fifth, sixth, and seventh volumes of his work, which comprehended his fourth book. These were devoted to the consideration of education, morals, and public instruction; and though on these important points we may be occasionally disposed to question his views, we must nevertheless admire his mild and philosophical spirit still opposed to every excess, his extensive knowledge, and his happy talent of arranging and combining it for the illustration of his argument; his animated, flowing, and perspicuous style; and, above all, that rectitude and philanthropy which are diffused over all his reasonings. His fifth book, which treated of the laws relative to religion, was soon afterwards published. But his health was now considerably impaired, owing to an excess of application, so that the remainder of his work advanced but slowly; and other interruptions soon followed. In the year 1787 he was called by the new king, Ferdinand IV., to the supreme council of finance. He returned to Naples, and from that time was wholly engrossed with the important business of this office. His health, already injured, was soon completely broken by severe and active application; and several domestic misfortunes operating upon a mind of deep sensibility, at last threw him into a state of melancholy. He finally retired from all business into the country, where he soon afterwards became seriously ill, and on the 21st of July 1788 he expired. Before his death he had finished the eighth volume of his work, containing the first part of the fifth book, in which he treats of the different systems of religion that preceded Christianity. Of the second part of the same book he had only made a rude sketch, in which were noted down the principal subjects of discussion; namely, the advantages of Christianity and the dangers of superstition; the inconveniences of mixing spiritual with temporal concerns; the excessive riches of the clergy, and the immense increase of their power. He was also to examine the foundation of ecclesiastical rights, and to present, in a new system of legislation, a remedy for the abuses which he pointed out. A chapter on toleration would have terminated this book. In his sixth book he proposed to treat of the laws relative to property; and in his seventh and last, of the nature of the paternal power and the government of families. He had also other important works in contemplation when his course was terminated by death. This eminent person, besides some of the rarest gifts of genius, was endowed by nature with the additional advantage of a most imposing presence. His manners were eminently graceful and dignified. His countenance bore the traces of habitual reflection, and of deep sensibility, mingled with an expression of soft melancholy. In private life nothing could exceed the simplicity of his character, except the animation and interest of his conversation. See *La Scienza della Legislazione*, Livorno, 1807, 5 tomes 8vo. This is the last Italian edition of Filangieri's great work. There is a French translation in 7 vols. 8vo, published at Paris in 1798, from the Neapolitan edition of 1784. The first two books have been translated into English, under the title of *The Science of Legislation*, from the Italian of Filangieri, and published in 2 vols. 8vo, Lond. 1806.

FILE, among mechanics, a tool used in order to smooth, polish, or cut metals. This instrument is of iron or forged steel, cut transversely in little furrows, with chisels and a mallet, and of a depth corresponding to the grain or touch required. After cutting the file, it must be tempered with a composition of chimney-soot, very hard and dry, diluted and wrought up with urine, vinegar, and salt, and the whole reduced to the consistence of mustard. Tempering files consists in rubbing them over with this composition, and in covering them with loam; after which they are put in a charcoal fire, and taken out by the time they have acquired a cherry colour, which is known by a small rod of the same kind of steel put in along with them. Being taken out of the fire, they are thrown into cold spring water, and subsequently cleaned with charcoal and a rag; after which they are kept dry and free from rust by laying them up in wheat bran. Iron filings require more heating than steel ones. Files are of different forms, sizes, cuts, and degrees of fineness, according to the different uses and occasions for which they are made.

FILIAL, something belonging to the relation of son.

Fi

Fil

Filial Piety.

Filial Piety, the affectionate attachment of children to their parents, including in it love, obedience, and assistance. These are duties prompted equally by nature and by gratitude, independently of the injunctions of religion; for where shall we find the person who has received from any one benefits so many or so great as children have from their parents? And it may be truly said, that if persons are undutiful to their parents, they seldom prove respectable in any other relation. Profane history furnishes many fine examples of this amiable virtue.

The Roman dictator T. Manlius having exercised great cruelty over the citizens, was cited at the expiration of his office to answer for his conduct. Amongst a number of things laid to his charge, he was accused of treating with barbarity one of his own sons. Manlius, according to Livy, had no other cause of complaint against this son than his having an impediment in his speech; for which reason he was banished from the city, his home, and the company of those of his own age and fortune, and condemned to perform servile works. All were highly exasperated against such inhuman conduct, excepting the son himself, who, under the greatest concern lest he should furnish matter of accusation against his father, resolved upon adopting a most extraordinary method to relieve him. One morning, without apprising any body of his design, he came to the city armed with a dagger, and went directly to the house of the tribune Pomponius, who had accused his father. Pomponius was yet in bed. Young Manlius sent up his name, and was immediately admitted by the tribune, who did not doubt but he was come to discover to him some new instances of his father's severity. But Manlius, as soon as he was left alone with the tribune, drew out his dagger, and presented it to his breast, declaring he would stab him to the heart on the instant, if he did not swear, in the form he should dictate, never to hold the assembly of the people for accusing his father. Pomponius, who saw the dagger glittering at his breast, and found himself alone, without arms, and attacked by a robust young man, full of confidence in his own strength, took the oath demanded of him, and afterwards confessed with a kind of complacency, and a sincerity which sufficiently showed that he was not sorry for what had happened, that it was this violence which obliged him to desist from his design.

Amongst the multitude of persons who were proscribed at Rome under the second triumvirate, were Cicero and his brother Quintus. But the latter found means to conceal himself so effectually at home, that the soldiers could not discover him. Enraged at their disappointment, they put his son to the question, in order to make him disclose the place of his father's concealment; but filial affection remained proof against the most exquisite tortures. An involuntary sigh, and sometimes a deep groan, was all that could be extorted from the youth. His agonies were increased, but with amazing fortitude he still persisted in his resolution of not betraying his father. Quintus was not far off; and it may be imagined how his heart must have been affected with the sighs and groans of a son expiring in tortures to save his life. He could endure no longer; and quitting the place of his concealment, he presented himself to the assassins, begging of them to put him to death, and dismiss the innocent youth, whose generous behaviour the triumvirs themselves, if informed of the fact, would judge worthy of the highest approbation. But the inhuman monsters, without being in the least affected with the tears of either the father or the son, answered that they must both die; the father because he was proscribed, and the son because he had concealed his father. Then a new contest of tenderness arose who should die first; but this the assassins soon decided, by beheading them both at the same time.

Cinna, who scrupled not to attempt any thing, however atrocious, which seemed calculated to serve his purpose, undertook to get Pomponius Strabo murdered in his tent; but his son saved his life; and this was the first remarkable action of Pompey the Great. The treacherous Cinna had, by many alluring promises, gained over one Terentius, a confidant of Pompey, and prevailed on him to assassinate the general, and seduce his troops. But young Pompey being informed of this design a few hours before it was to be put in execution, placed a faithful guard round the prætorium, so that none of the conspirators could come near it; then watched all the motions of the camp, and endeavoured, by acts of prudence worthy of the oldest commanders, to appease the fury of the soldiers, who hated the general his father. However, some of the mutineers having forced open one of the gates of the camp, in order to desert to Cinna, the general's son threw himself flat on his back in their way, crying out that they should not break their oath and desert their commander, without treading his body to death. By this means he put a stop to their desertion, and afterwards wrought so effectually upon them by his affecting speeches and engaging demeanour, that he reconciled them to his father.

Olympias, the mother of Alexander, was of such an unhappy disposition, that he never allowed her to have any concern in the affairs of the government. She used frequently to make great complaints on this account; but he always submitted to her ill humour with great mildness and patience. Antipater, one of his friends, having one day written a long letter against her to the king, then absent, Alexander, after reading it, replied, "Antipater does not know that one single tear shed by a mother will obliterate ten thousand such letters as this." Behaviour like this, and the answer here recorded, show that Alexander was both an affectionate son and an able politician.

Epaminondas is universally acknowledged to have been one of the greatest generals and best men whom Greece ever produced. Before him the city of Thebes was not distinguished by any memorable action, and after him it was more famous for its misfortunes than its virtues, till it sunk into its original obscurity; so that its glory may be said to have arisen and expired with this great man. The victory which he obtained at Leuctra had drawn the eyes of all the neighbouring states upon Epaminondas; they looked upon him as the support of Thebes, the triumphant conqueror of Sparta, and the deliverer of Greece; in a word, as one of the greatest men and the most excellent captains the world had ever produced. But, in the midst of this universal applause, so capable of making the general of an army forget the man, Epaminondas, little sensible of so affecting and so deserved a glory, observed, "My joy arises from my sense of that which the news of my victory will give my father and my mother."

Amongst an incredible number of illustrious persons who were falsely accused and put to death by Nero, was one Bareas Soranus, a man of singular vigilance and justice in the discharge of his duty. During his confinement, his daughter Servilia was apprehended, and, being brought before the senate, was there arraigned. The crime laid to her charge was, that she had converted into money all her ornaments and jewels, and the most valuable part of her dress, to defray the expense of consulting magicians. To this the young Servilia, with tears, replied, that she had indeed consulted magicians, but the whole of her inquiry was to know whether the emperor and senate would afford protection and safety to her beloved and indulgent parent against his accusers. "With this view," said she, "I presented the diviners, men till now utterly unknown to me, with my jewels, apparel, and the other ornaments peculiar to my quality, as I would have presented my blood and my life, could my blood and life have procured my father's liberty. But whatever this my proceeding was, my unfortunate father was an utter stranger to it; and if it is a crime, I alone am the delinquent." Notwithstanding this affecting appeal, she was condemned to die along with her father, but in what manner history is silent.

Valerius Maximus likewise mentions a very singular circumstance relating to this subject. A woman of illustrious birth had been condemned to be strangled. The Roman prætor delivered her up to the triumvir, who caused her to be carried to prison, in order that she might be put to death. But the jailor, who was ordered to execute her, being struck with compassion, could not resolve to kill her, and chose therefore to let her perish of hunger. Besides this, he suffered her daughter to see her in prison, taking care, however, that the former brought nothing in the shape of sustenance. As this continued many days, he was surprised that the prisoner should live so long without eating; and suspecting the daughter, he discovered, on narrowly watching her motions, that she nourished her mother with her own milk. Amazed at so pious, and at the same time so ingenious an invention, he mentioned the fact to the triumvir, and the triumvir to the prætor, who believed the thing deserved being mentioned in the assembly of the people. The criminal was pardoned, and a decree was passed that the mother and daughter should be subsisted for the rest of their lives at the public expense.

The same author gives a similar instance of filial piety in a young woman called Xantippe towards her aged father Cimonus, likewise confined in prison, and which is commonly known by the name of the *Roman charity*. Both these instances appeared so extraordinary to that people, that they could only account for them by supposing that the love of children to their parents was the first law of nature. *Putaret aliquis*, says our author, *hoc contra naturam factum esse, nisi prima naturæ lex esset diligere parentes.*

FILIBEG, or Philibeg. See Philibeg.

FILICAIA, Vincenzo da, a celebrated Italian poet, descended of a noble family of Florence, was born in that city on the 30th of December 1642. He commenced his studies under the Jesuits at Florence, and completed them in the university of Pisa. Grecian and Roman antiquity, philosophy, theology, and jurisprudence, were successively the objects of his study; poesy served merely as a relaxation from severer pursuits. Like most young devotees of the muses, he began with amatory verses; but the lady whom he loved and celebrated having died in the flower of her age, he burned all the verses which he had inscribed to her, and resolved henceforth to sing only heroic or sacred themes, a resolution which he most religiously observed. Having returned to Florence, after a residence of about five years at Pisa, he was received into the academy Della Crusca, and, in a short time, married a daughter of the senator Scipio Caponi; but as this lady brought him little fortune, and his own means were limited, he withdrew entirely from the world, on the death of his father, and established himself in the country, where he divided his time between his studies, the education of his children, and the contemplation of the wonders of nature and its author. He every day composed verses either in Latin or Italian, which he submitted to the judgment of his friends, and improved according to the advice which they gave, without any desire for publication, or indeed any other object than that of exercising his own powers. But a memorable occurrence drew him from the voluntary obscurity in which he had buried himself. Vienna, besieged by an army of two hundred thousand Turks, was delivered by John Sobieski, king of Poland, and by the Duke of Lorraine, afterwards Charles V. This great event, which saved Christendom from the most imminent danger, excited the enthusiasm of Filicaia, who, in a magnificent *canzone* or ode, celebrated the victory of the Christian armies; he also addressed a second to the Emperor Leopold I., a third to the King of Poland, a fourth to the Duke of Lorraine, and a fifth to the god of armies; and the Ottomans, having been entirely defeated in another battle, he celebrated this new triumph in a sixth ode, which is perhaps the most beautiful of all. These six triumphal odes excited universal admiration. The grand duke, of his own accord, sent copies of them to the princes whose exploits were commemorated, and from the latter the author received the most flattering acknowledgments. But as the copies of his odes became daily deformed by new errors, in proportion as they were multiplied, his friends at length obtained permission to print them. They accordingly appeared at Florence, in 1684, in 4to; and Filicaia was, almost in spite of himself, placed in the first rank of Italian lyric poets. Another great ode, which he addressed the same year to Queen Christina of Sweden, fully supported the reputation which he had gained by his former productions. This princess, who then exhibited in private life the generosity of a sovereign, did not confine herself to a mere expression of her satisfaction, or corresponding with the author, or admitting him into the academy, which she had formed at Rome, of men most distinguished in poetry and letters; being informed of the depressed state of his circumstances, she in some sort adopted his two sons, undertook to defray the expense of their education, and exacted from their father, as the only expression of his gratitude, that he would maintain the most profound silence, not chusing, as she said, to have to blush before the public for having done so little to serve a man who had so many claims to her esteem. But a severe malady with which he was seized some years afterwards, was followed by another subject of affliction, which he felt much more sensibly; he lost his eldest son, who had been appointed page to the grand duke after the death of the queen his benefactress. This bereavement, which he bore with Christian fortitude, fixed on him the particular attention of the prince, who, interested in his fortune, conferred on him the dignity of senator, and soon afterwards appointed him ducal commissary of Volterra, then commissary of Pisa, and, lastly, secretary *au tirage* to the magistrates, an important office, which gave him immediate access to the prince, and initiated him in the secrets of the government. Filicaia, in all his employments, secured at once the gratitude of the public, the attachment of those under him, and the esteem of his sovereign. Neither the multiplicity of his occupations, nor the progress of age, however, prevented him from dedicating several hours each day to the cultivation of letters and the exercise of his poetical talent; but as his piety, which had always been great, increased with his years, he at length confined his reading to religious books, and treated only of sacred subjects. Nevertheless, he had resolved to collect all his pieces, to revise and correct them of new, and to publish himself a complete edition of his lyrical composition; but, whilst occupied with this undertaking, in which he had made considerable progress, he was seized with a violent affection in the chest, which in a few days put a period to his life. He died at Florence, on the 24th of September 1707, in the sixty-fifth year of his age, and was interred in the family vault in the church of St Peter, where his son Scipio erected a monument to his memory. The edition of his poetical works in Italian, which he was preparing, and had even begun to print at the time of his death, was also speedily published by the same son, who dedicated it to the Grand Duke Cosmo III. under the title of *Poesie Toscane de Vincenzo da Filicaja, senatore Fiorentino et acceademico della Crusca*, Florence, 1707, in 4to. They were reprinted in

1720, with a life of the author, by Thomas Bonaventuri, a Florentine; which life had previously appeared in the second volume of the *Vite degli Arcadi Illustri.* But a more valuable though less beautiful edition, from which all the subsequent editions have been taken, is that of Venice, 1762, in two volumes 8vo; the first of which contains the *Poesie Toscane*, and the second, the Latin verses of the same author, there for the first time collected from the different publications in which they had been previously scattered. There are subjoined some pieces in prose of inferior interest, if we except a literary correspondence of Filicaia with Francesco Redi, Menzini, and Gori, who shared with him the glory of having, in a corrupt age, remained faithful to the principles of good taste and sound literature. The *canzoni*, to which we have above referred, are perhaps the most remarkable compositions in this collection; but some of the other pieces are not inferior to these either in the dignity of the subject or the majesty and force of the style; and several of his *Sonnets* are worthy of these beautiful odes. Is there an Italian heart that can be insensible to the deep patriotic feeling, expressed with such a mournful and affecting sublimity, in the well-known sonnet commencing

> Italia, Italia, O tu cui feo la sorte
> Donno infelice di Bellezza, etc;

one of the most perfect compositions of the kind in existence, and which, though it consists of only fourteen verses, will sustain a comparison with the most celebrated lyrical effusions, ancient or modern?

FILIGRANE, Filigree, or Fillagree, Work, a kind of enrichment on gold or silver, wrought delicately in the manner of little threads or grains, or both intermixed. The word is compounded of *fil* or *filum*, a thread, and *granum*, a grain, and in Latin is called *filatim elaboratum opus, argentum, aurum.*

There is no manufacture in any part of the world which has been more admired and celebrated than the fine gold and silver fillagree of Sumatra; and what renders it a matter of still greater curiosity, is the coarseness of the tools employed in the workmanship, and which, in the hands of an European, would not be thought sufficiently perfect for the most ordinary purposes. They are rudely and inartificially formed by the goldsmith, from any piece of old iron which he can pick up. When one of them is engaged to execute a piece of work, his first request is usually for a piece of iron hoop to make his wire-drawing instrument; an old hammer head, stuck in a block, serves him for an anvil; and his pair of compasses is often composed of two old nails tied together at one end. The gold is melted in a piece of *preeoo* or earthen rice-pot, or sometimes in a crucible of ordinary clay. In general no bellows are used, but the fire is blown with the mouth, through a joint of bamboo; and if the quantity of metal to be melted is considerable, three or four persons sit round the furnace, which is an old broken quallee or iron pot, and blow together. At Padang alone, where the manufacture is most considerable, they have adopted the Chinese bellows. The method of drawing the wire differs but little from that which is used by European workmen. When drawn to a sufficient fineness, it is flattened by beating it on the anvil; and when flattened, a twist is given to it like that in the whalebone handle of a punch ladle, by rubbing it on a block of wood with a flat stick. After twisting they again beat it upon the anvil, and thus it becomes flattened wire with indented edges. The end of the wire is folded down with a pair of pincers, and thus is formed a leaf, or element of a flower in their work, which is cut off. The end is again folded and cut off, till they have got a sufficient number of leaves, which are laid on singly. Patterns of the flowers or foliage, in which there is seldom much variety, are prepared on paper of the size of the gold plate on which the fillagree is to be laid. According to these, they begin to dispose on the plate the larger compartments of the foliage, for which they use plain flattened wire of a larger size, and fill it up with the leaves before mentioned. In order to fix the work, they employ a gelatinous substance, made of the red-hot berry called *boca sago*, ground to a pulp on a rough stone, which pulp they place on a young cocoa nut about the size of a walnut, the top and bottom being cut off. After the leaves have been all placed in order, and stuck on bit by bit, a solder is prepared of gold filings and borax moistened with water, which is strewed over the plate, when it is put in the fire for a short time, and the whole becomes united. This kind of work on a gold plate is called *carrang papan;* but when the work is open, it is called *carrang trouse.* In executing the latter, the foliage is laid out upon a card, or soft kind of wood, and stuck on, as before described, with the sago berry; and the work, when finished, being strewed over with the solder, is put into the fire, when the card or soft wood burning away, the gold remains connected. If the piece be large it is soldered at several times. In the manufacture of badjoo buttons, they first make the lower part flat, and having a mould formed of a piece of buffalo's horn, indented to several sizes, each like one half of a bullet mould, they lay their work over one of these holes, and with a horn punch press it into the form of a button; after which they complete the upper part. When the fillagree is finished they cleanse it by boiling it in water with common salt and alum, or sometimes lime juice; and in order to give it that fine purple colour which they call *sapo*, they boil it in water mixed with brimstone. The manner of making the little balls with which their works are sometimes ornamented, is simple. They take a piece of charcoal, and having cut it flat and smooth, make in it a small hole, which they fill with gold dust, and this being melted in the fire, becomes a little ball. They are very inexpert at finishing and polishing the plain parts, hinges, screws, and the like, being in this as much excelled by the European artists as the latter fall short of them in the fineness and minuteness of the foliage. The Chinese also make fillagree mostly of silver, which looks elegant, but wants the extraordinary delicacy of the Malay work. The price of the workmanship depends upon the difficulty or uncommonness of the pattern. In some articles of usual demand it does not exceed one third of the value of the gold, but in matters of fancy it is generally equal to that of the metal.

FILIPPO D'ARGYRO, a city of the province of Catania, in the island of Sicily. It is situated on the summit of a lofty insulated hill, abounds in churches and monasteries, contains 6118 inhabitants, and produces near it much saffron and good wine. It was the birth-place of the celebrated historian Diodorus Siculus.

FILLET, or Filet. See Architecture, *Index.*

Fillet, in *Heraldry*, a kind of orle or bordure, containing only a third or fourth part of the breadth of the common bordure. It is supposed to be withdrawn inwards, and is of a different colour from that of the field. It runs quite round, near the edge, as a lace over a cloak.

Fillet is also used among painters, gilders, and others, for a little rule or reglet of leaf gold, drawn over certain mouldings, or on the edges of frames, pannels, and the like, especially when painted white, by way of enrichment.

Fillets, in the *Manège*, are the loins of a horse, which begin at the place where the hinder part of the saddle usually rests.

FILM, a thin skin or pellicle. In plants it signifies that thin woody skin which separates the seeds in the pods, and keeps them apart.

FILOTI, a town of the Turkish province Yanina, and the capital of a district of the same name. It contains

4000 inhabitants, who make excellent oil, and cultivate a considerable extent of tobacco.

FILTER, an instrument or apparatus contrived for clearing liquids from any impurities mechanically combined with them. Filters are of various kinds, according to the nature of the liquor requiring to be clarified; but they all act on the same general principle, namely, straining the liquor by passing it through earth or other porous material; the process being thus exactly analogous to that of sifting, as used for powder or other dry substances. The operation of filtering is extensively used in chemistry and the arts, and also in purifying water for domestic purposes, and for the use of ships in long voyages; and hence the construction of artificial filters on a large scale for the supply of towns and cities with pure water becomes a very nice and difficult operation, and now forms an important branch of civil engineering. The pureness of spring water arises entirely from a process of filtration. Such water generally issues from a considerable depth beneath the surface of the ground, as is evident from the force with which it is discharged, and the equable temperature which it preserves throughout the year, being cool in summer, and in winter never freezing. Hence, in its course from the surface downwards, it must pass through a variety of soils, subsoils, and porous rocky strata; and it is by the perfect straining which it receives in percolating through such vast masses of filtering materials as must occur in the bowels of the earth, that it comes out at last with that admirable purity and transparency which we observe. But notwithstanding of this, spring water contracts, often among the rocks and minerals with which it comes in contact, various impurities, which become chemically dissolved in it, and from which it cannot be freed by filtration or any other mechanical process. It becomes often, therefore, unfit on this account for domestic use or the purposes of the arts, and is rarely equal, and never superior, to rain or river water properly filtered. The great importance of this operation, therefore, is evident, more especially from the frequent and serious failures which have taken place. But it may be better to defer the consideration of this branch of the subject till it can be resumed along with other hydraulic operations. See WATER-WORKS.

Water filters for domestic use.

On a smaller scale, for domestic use, water filters have at different times been brought forward, and for many of them patents taken out. But as they are all very similar in principle, and none appears greatly distinguished above the rest, it is unnecessary to enter into a minute description of them. They are all liable to the objection of clogging up, and getting foul in the course of time. But if regularly cleaned, any of them will answer the purpose sufficiently well, the process of filtration being so simple and so easily effected. Several ingenious plans have been proposed for self-cleaning filters; the water, for instance, being made to ascend, or to pass alternately in opposite directions, and thus carry off the impurities by the process itself. But as none of these have succeeded completely, it will be found most convenient in small filters to clean them regularly; and those are therefore to be preferred which afford the means of doing this most conveniently.

Filtering materials.

In these filters the filtering material generally used is gravel, sand, porous stone, or unglazed earthenware. Charcoal is sometimes added, but this is more for its antiseptic and purifying quality, and is only necessary in the case of fetid or very impure water. Gravel, though the best of all materials on a large scale, is rather coarse in itself for small filters. But where it occurs in nature in very thick beds, the large mass of material makes up for the coarseness of the grain; and many instances occur where springs from this source are scarcely inferior in purity to distilled water. But in small filters it requires a bed of sand above it to detain the impurities. Sand is perhaps, after all, the best filtering material; it should, however, be clean sea or river sand, with no tincture of iron; this last is indicated by its reddish colour, which, if deep, will communicate an iron taint to the water, a circumstance harmless enough in itself for most domestic uses, but very prejudicial for the purposes of bleaching, paper-making, &c. in the arts.

Sand, gravel ters.

In filters constructed with gravel or sand, all the apparatus that is necessary is a vessel to contain the filtering material, with a space above for holding a quantity of the water to be filtered, and a vessel below for receiving the filtered water. A simple and convenient apparatus of this kind was contrived by Messrs Hearman and Dearn, potters, Redriff, described in Nicholson's *Journal*, vol. viii., and represented in Plate CCXLV. fig. 1, which exhibits the whole apparatus, and shows, in fig. 2, a shaded section. A is a vessel of stone-ware perforated with holes, *m*, at bottom, upon which coarse gravel, *h*, is laid, and on that again a stratum of fine gravel, and, lastly, fine sand, *g*. Or, otherwise, the bottom may be covered with a coarse cloth, which will render the graduated fineness of the gravel and sand less necessary. Upon the top of the sand is laid a perforated and loaded board or plate of earthenware, to prevent the sand from being disturbed when the water is poured in. B is a lower vessel, into which the filtered water from A drops, together with any sand that may escape from above. The clear water flows out through the neck *ac* into the vessel *d* for use.

On this plan an excellent filtering apparatus may be constructed at little expense, and in various ways, according to the means or conveniencies most readily at hand; and the sand and gravel possess a decided advantage over filtering stones or other materials, from the great facility of cleaning, the latter being liable, from long use and the impurities lodging in their pores, to give the water an unpleasant taint.

A very simple arrangement in the above plan is to have a cylindrical jar of earthenware, as at fig. 5, with two partitions or false bottoms, dividing the height into three equal portions, the partitions resting each on a shoulder formed all round on the jar, or otherwise supported; the middle division for the filtering material, the upper one for the water to be filtered, and the lower one for containing the filtered water, with a stop-cock for drawing it off at pleasure, and a vent or opening at the top for the admission and discharge of air. The stop-cock must be placed three or four inches from the bottom, to allow full space for any sand or other material to deposit in the bottom; and the air vent must be carried up by a small pipe to the top of the jar, to prevent the water ever rising and overflowing by it. The partitions are made of earthenware, with a number of small holes to allow the water to descend. If sand only is used, it will be necessary to spread a layer or two of cloth under it, to prevent the sand getting through the openings. But if gravel can be had, it will be better to lay a bed of this, of two inches or more in thickness, on the bottom, and the sand above it. After the sand is filled in to the height of the upper partition, this is placed on as a cover, which having also a number of small openings in it, the water flows from the upper division downwards. The cover should press on the top of the sand, in order to prevent its being disturbed by the entrance of the water, or a layer of gravel should be placed on the top of the sand. If a layer or two of cloth be laid over the partition, it will serve to detain some of the impurities; and being frequently washed, it will make the filter continue longer clean. In order to clean this filter it is only necessary to remove the upper partition, take out the upper stratum of sand to the depth of two or three inches, wash it thoroughly, and replace it; or, if sand can be had readily, let the whole be replaced with a fresh quantity, clean and pure. This is, on the whole, a very simple, perfect, economical, and convenient filter. It may be constructed of wood or other convenient material, and is both very easily formed, and easily kept clean and in order; and by varying the thickness of the bed of sand, it can be adapted to the exact degree of filtration required. The vessel also admits of any ornamental shape which taste may direct; and several elegant figures of this kind, contrived by the manufacturers, are shown at the bottom of the plate. If the lower division also were left unglazed and porous, an evaporation would go on from the outside, so that in summer it would act as a cooler as well as a filterer. Should much sediment be found collecting in the lower vessel, perhaps it would be better to place the whole apparatus upon a second jar, so wide as to allow the first to stand over it, and having a pipe in the bottom rising nearly to the top of the vessel, and open at the top. The filtered water would flow over this, and descend into the lower vessel, which being detached, could always be kept perfectly clean in the bottom. The upper end of the pipe should be covered with a fold or two of cloth. An ingenious plan, introduced by Mr Parkes, chemist, for drawing off the water in the reservoir of a filtering or purifying apparatus, though applied rather on a larger scale, might often be used with advantage in smaller filters, such as those for bleachers, paper-makers, and others. It is represented at fig. 6, and consists in connecting the stop-cock for the discharge of the water with a pipe and flexible joint terminating in a rose-head and floating ball, which keeps the head always immersed a little under water, and thus discharges it from near the surface, although the level of the water may vary considerably. The water here is also let in, not directly into the reservoir, but by an upright pipe having a funnel at the top, and descending to near the bottom, which causes the water to enter below, where it must deposit any impurity before this can rise to the surface.

Filterin by desc and asce

In the sand and gravel filters here described, the water descends during the whole of the process, and this causes a slight tendency to carry minute particles of sand or other impurities along with it. To remedy this defect, various plans have been proposed for making the water, after descending, again ascend; and this plan certainly possesses advantages, and is a decided improvement on the other. A very neat contrivance of this kind is that proposed by Professor Parrot of Paris, in Nicholson's *Journal*, and is represented at fig. 3.

By Pro sor Parr

It consists simply of an inverted syphon, which could be easily made of lead, having the bend filled with sand, and being covered on the top with gravel in each branch. The water entering the longer branch from a reservoir, passes through the sand, and rising up, is discharged at the other end, which should be three inches below the level of the first. When the section of the tube is four inches by two, and eighteen inches the length of sand, it was calculated that six Paris pints of pure water would be passed in an hour.

By Sir Englefie

Another plan, proposed by Sir Henry Englefield, in the same work, is shown at fig. 4. It consists of a conical vessel placed within the one containing the sand, and allowing the water to descend on the inner vessel, and ascend again in the outer one.

But the simplest mode of effecting the ascent of the water is merely to divide the jar or filtering vessel by a vertical partition, open at the bottom. The water being then poured into the one side, descends to the bottom, passes under the partition into the other side, and ascends to the same level at which it entered, and can then be drawn off by a stop-cock or other means at pleasure. In that case a single vessel only is wanted, and contains in itself the means of holding separately the filtering material, the water to be filtered, and the water after filtration. Upon the whole, this appears by far the simplest, most perfect, most economical, and most convenient filter of this, or perhaps of any kind, that can be contrived. All that is necessary is to have a pretty deep vessel of earthenware, wood, or other material; a tub or barrel will answer perfectly. Put a vertical partition in the middle, reaching nearly to the bottom, fill it half or three fourths full of sand, with a layer of gravel on the top, and it is ready for use. It may be found convenient, to prevent the gravel being disturbed, to place a cover over it, with holes. The water may either be drawn directly from the pure side with jugs, or let off by a stop-cock. Instead of sand and gravel, some have proposed to use charcoal, either by itself or in combination with the others; and an apparatus of this kind was contrived by Mr John Isaak Hawkins. It is only, however, when the water has an impure taint, which cannot be removed by sand, that the charcoal should be resorted to, as it is more expensive, and more difficult to be cleaned. In long voyages, however, charcoal, as proposed by Hawkins, may, in conjunction with sand, be found very useful.

Charcoal filter by Mr Hawkins.

Filtering by ascent alone.

Instead of the water descending and then ascending, several ingenious methods have been contrived where the water only ascends through the filter, being let in below, and forced upwards by the pressure of an external head of water. The advantage of this is, that the filter can be cleaned by letting the water return and run out at the place where it usually enters. These plans, however, on a small scale, are hardly ever found to supersede cleaning. On this principle was the patent granted in 1791 to Mr Peacock, which he intended for small filters as well as those on a large scale. His apparatus consisted of a vessel of wood, lead, or other materials, of any shape or dimensions required, divided near the bottom by a horizontal grate or partition, upon which the filtering medium was spread in layers, beginning with the coarsest and ending with the fine. The lower division had a communication with a more elevated reservoir, from which the water flowed, and rose through the filtering bed. This consisted of gravel, sand, broken and pulverized glass or pottery, all well washed and sifted with sieves. On a similar principle Mr Bramah had a patent for various modes of conveying and drawing off beer and other liquors, in which he describes a filtering apparatus which he proposed to place in the pipes to conduct the liquor. This was a cylindrical vessel, made of copper tinned within, or of any other materials; the upper end was closed by a lid screwed on by a flaunch, and the lower end terminated in a cone; a pipe was inserted into the vessel near the lower part, to introduce the liquor; and from near the upper end a similar pipe proceeded to convey it away. Between these two was fixed the filtering floor, consisting of flannel, sand in bags, sponges or other similar substances, which were spread upon a horizontal plate pierced full of small holes, and fixed in the cylinder above the filtering substance; and another similar plate was fixed and screwed down to confine it. The liquor was introduced by the lower pipe by means of a pump or otherwise, and ascending through the filtering floor, passed off in a clarified state; the impurities which are separated collect in the conical bottom of the cylindrical vessel, whence they can be drawn by a cock. This contrivance is adapted to give a slight filtration to a great quantity of liquor, such as beer; and Mr Collier, in a patent for the purification of oils, claimed the principle of filtering *per ascensum* combined with hydrostatic pressure.

Mr Peacock.

Mr Bramah.

Mr Collier.

Filtering stones.

Such are the different contrivances for filtering water, where sand and gravel are the materials; but notwithstanding their simplicity, filters of porous stone are those which have hitherto been most generally in use. The stones are procured from beds of sandstone, and sometimes a kind of limestone. They are found in Northamptonshire, Derbyshire, and other parts of England, and are often imported from the island of Teneriffe. The construction of the filter is extremely simple. A thick bowl or basin is formed of the stone, and mounted in a frame. The foul water, being poured into the basin, passes slowly through the substance of the stone, and drops into a receptacle below, in a perfectly transparent state. When the water is foul, a small quantity of mud or slime is found to collect at the bottom of the basin, and must occasionally be cleared out; but in the course of time the more minute impurities will insinuate themselves into the pores of the stone, and at last clog up the passage of the water. This is remedied by chipping away the interior surface of the stone one half or three fourths of an inch, because the impurities do not penetrate deeper into the stone. This will restore its action for a long time.

The basin shape used in these filters is obviously not the most proper, as it leaves an unequal thickness in the bottom for the water to penetrate, and also the pressure of the fluid is unequal. The bottom should be flat and of equal thickness, and in fact it would be much better not to make the stone a reservoir at all; but to use a filtering vessel such as above described, substituting for the sand and gravel a plate of the filtering-stone, of such thickness as may be found best adapted for the nature of the water. If a thin plate also were placed on the top of a thick one, it might then be removed without any trouble when it got foul, and replaced by another, without disturbing the lower mass; or several plates could be laid one above another till the requisite thickness for filtering were obtained.

Filtering upwards.

Instead of pouring the water into the basin and allowing it to filter downwards, the water may be contained in a vessel in which the basin is nearly immersed; and in this way the water will filter partly laterally, but chiefly *per ascensum*, and leave much of its deposit behind, so as to enable the stone to continue longer clean. A filter on this plan was contrived by Mr Moult, and is described in the Transactions of the Society of Arts. The filtered water runs in and fills the basin, from which it can be taken out or let off by a pipe. This principle was also proposed by Mr Collier, and it possesses all the advantages we have already described in filtering upwards with sand; and if it were used with plates of the stone instead of a basin, it would be still more effectual.

Anglesea earthenware filters.

The unglazed earthenware for filtering has been introduced as a substitute for the filtering stones. It is made of different compositions of pottery. The original patent was granted to Mrs Johanna Hempel, potter, Chelsea, in the year 1790. The proportions were four out of nine of tobacco-pipe clay, and five out of nine of coarse sea, river, or pit sand. This was intended for basins not exceeding one gallon. For larger capacities it is liable to fly or crack in the fire. A second composition, therefore, consisted of equal parts of tobacco-pipe clay and sea or river sand; or if this was found insufficient to prevent the cracking, three parts tobacco-pipe clay, one of Stourbridge clay, or clay from the surface of the coal mines, one of Windsor loam, or other loam of equal quality, and four of coarse river or sea sand; or four parts of tobacco-pipe clay, three of sand, and one of the burnt ground clay of which crucibles are made. The above ingredients are brought to the proper basin or bowl shape on the wheel, and are then hardened in the furnace like other pottery ware. The same objection, however, applies here to the basin shape as to the stones; in fact, it would be better to have this composition formed into plates of different thickness, which could then be used, one or more in number, in the filtering vessels, instead of sand or stone; one could be taken out when foul, and another put in, with the utmost facility; and this would certainly be attaining the perfection of a filtering apparatus.

Another still simpler plan would be to have one filtering vessel, with a vertical partition of the porous ware reaching to the bottom. The one half of the vessel would then be filled with the impure and the other with the pure water; and if several of these plates were at hand, one partition could be taken out when foul, and another inserted in its place, or there might be two porous partitions, and a solid one between them. The one would then ascend and run over the top of the solid partition, and again descend and pass through the second porous partition, which would therefore hardly ever require renewal.

A filter by Mr Robins of London, and for which he has taken out a patent, has been lately much recommended to the public. The external appearance is varied according to taste, and figs. 13, 14, 15, already referred to, represent some of the neatest and most elegant patterns. We are not acquainted with the interior construction, but understand it consists of various strata of filtering material, such as we have above described, arranged so as to act with peculiar efficacy. At the top there is a sponge neatly inserted into a recess above the upper partition, which is a very judicious and useful mode of detaining any impurities, and preventing them from getting into the filterer, the sponge being easily taken out and washed from time to time. The patentee, however, claims far higher powers for his invention than that of mere filtration. He states that the interior process involves a *voltaic* action, which decomposes soluble substances, and renders the water equal in purity to distilled water. We confess we have great doubts in regard to this, and think it irreconcilable with any idea of voltaic or chemical action with which we are acquainted. Still we have no doubt, from the various testimonials brought forward, that the filter is a good one. Fig. 14 is about three feet high, and one and a half broad, and is calculated to filter fifty gallons a day; the others in proportion.

From the great success with which water has been purified by filtration, attempts have been made to purify oils in the same manner; and an ingenious apparatus for this purpose was contrived, and a patent taken out, by Mr Joshua Collier, applicable also to water and other liquids, and of which an account will be found in the *Repertory of Arts*, vol. x. But in oils there is generally so many impurities, chemically or otherwise united, that filtration can do little for their purification. Charcoal is the substance chiefly employed. A filtering machine contrived by Mr Innes of Edinburgh is said to answer well for oils and other fluids. By it the fluid is forced through the pores of wood by the action of a forcing-pump. Such a degree of pressure is unnecessary for water; but for oil, quicksilver, and other valuable fluids, it appears certainly well adapted.

Filtration is much used in chemical processes. The materials employed are unsized paper, cloth, flannel, tow, sponge, sand, pulverized glass, flints, porous stones, earthenware, &c. In fig. 12 is represented a neat little filtering apparatus constructed by Mr Parkes; and the following remarks and directions are taken from Mr Faraday's excellent work on Chemical Manipulation. "Of the above substances, the first is almost exclusively in use at the laboratory, a few of the others now and then being resorted to only on particular occasions.

"Funnels are continually necessary to support the paper through which filtration is to take place. The ordinary funnels required in the laboratory for the passage of fluids answer the purpose very well, but they are of use for supporting filters, when, from their necks being broken off, they are otherwise unserviceable. They may be either of glass or good Wedgewood or other earthenware; those of glass are to be preferred, because the progress of the filtration and the state of the filter can be better ascertained in them. Metal funnels should not be allowed in the laboratory.

"The funnels containing filters may be frequently supported by the glass or jar intended to receive the filtered fluid, and at other times by the rings of retort stands. But notwithstanding these facilities, so frequently is the operation required, a laboratory should be supplied with at least one filtering stand of considerable size. The end of such a stand is represented in fig. 7. It should be fifteen inches wide, three or four feet long, and have an interval between the bottom and top of twelve inches. The top should have a number of round holes made in it at intervals of six inches, differing in diameter from one and a half to three inches; two or three small ones of half an inch or an inch in diameter being intermixed. The whole should be well made and firm, so as to support considerable weights, the top having frequently to answer the purpose of a table, and to sustain jars full of solutions, as well as to bear funnels and filters.

"It is no easy matter for the chemist to obtain unobjectionable filtering paper, and yet it is of such importance in reference to the duties it has to perform, that he should not spare pains to procure the best possible. It should be so porous as to admit the free and ready passage of fluids; so close as to retain the finest solid particles; so strong as to bear the weight of a considerable quantity of fluid; and so pure as to give nothing to the solution, or if heated with the substance retained upon it, to occasion no mixture of ashes. Some chemists use plate paper, that is, the paper of copperplate printers. It is very porous, and yet there are few precipitates that will pass through it; at the same time it is often tender, generally yields a considerable quantity of ashes when burnt, and is inapplicable for minute filters when very small quantities of fluid only are to be worked upon, because of its thickness, and consequent waste of the portion of solution imbibed by it.

"It is amongst the thinner varieties of unsized paper, or white blotting paper, kept by some of the stationers, that the chemist will probably find the kind best suited to his purpose. It should be so strong, that a single filter of it, capacious enough to hold a pint of water, should not break with that quantity, even though some degree of agitation be given to the funnel containing it. Its porosity, that is to say, its comparative freedom from size, for it is mostly sized in a slight degree, may be judged of by holding it to the tongue, and observing how it absorbs moisture; and by a cautious pull its strength may be ascertained whilst in such moistened state. The student who is unused to the examination of papers will, however, better judge of its capability of allowing fluid to pass, by actual trial with water; a pint filter filled with clean water should allow the fluid to run in a considerable stream.

"The best method of judging of the purity of paper is to burn it and examine its ashes: the fewer it yields the better is it adapted for filters. A demy sheet should not yield more than one and a half or two grains of ashes altogether. If it contains more, their solubility or insolubility should be observed, that the student may be aware of the impurities that may probably be imparted to solutions in very delicate experiments. In minute cases of investigation, sulphuric acid may frequently be traced to the sulphate of lime existing in the filtering paper.

"Filtering paper should be cut ready for use into different sizes. A demy paper furnishes useful sizes for filters, when the sheet is separated into four, or six, or nine parts; and parcels of each of these sizes being prepared, they should have a string passed through the corners, and be preserved for use in a clean place. The previous cutting of the paper in this way is very convenient, as readily supplying the sizes that will be wanted, and in preventing the waste that would occur by carelessly tearing up a sheet each time a filter is required.

"On preparing a filter, the piece of paper should be first examined, by looking through it against the light, to ascertain that it is free from holes. The simplest filter is made by folding the paper twice in opposite directions, so as to bring the four corners together, and by opening one corner from the other three, so as to produce an irregular conical cavity, as in fig. 8. Such a filter being put into a funnel, and then filled with liquid, will immediately permit its passage; but from the similarity of form between the filter and the funnel, and the close adhesion of the former to the latter over by far the greater part of its surface, considerable obstruction is opposed to the passage of the fluid, and the operation is retarded. For this reason different contrivances have been recommended, to separate the filter here and there from the funnel, and allow passages for the fluid. Lavoisier recommended small glass rods inclined along the funnel before the filter is put in. Straws are used in a similar way, and they certainly open channels in their immediate neighbourhood, by which the fluid may flow down. By other chemists ribbed funnels are recommended; but it is difficult to find a funnel so deeply ribbed as to support the paper in such a manner that it shall not touch the glass in every part, and if they do not perform this they are of no use.

"The best expedient by far is so to fold the filter that ribs may exist in the paper itself; and this may be done so as not only to allow numerous free passages for the fluid between the filter and the glass, but also to allow of ready transmission through its whole surface, and not of one half only, and even that imperfectly, as in the former case. For this purpose, the paper is first to be doubled, and in this state is again to be folded in half, each half folded into quarters, and each quarter into eighths, the folds being all on the same side, and radiating at equal distances from the middle of the folded edge to the other edges. Fig. 9 represents the doubled paper thus divided into eight parts. Each eighth is now to be divided into half by folds in the opposite direction, but in lines still originating at the same centre, which makes the doubled piece resemble a child's paper fan, both when closed and when a little open: it is represented by fig. 10. Whilst in this state, the projecting corners should be taken off by a knife; folding the whole up tight like a closed fan, and making the section at about *a*. Being now allowed to expand a little, the originally doubled sides are to be separated from each other for the first time, but without disturbing the angles or bending the ridges or ribs which they form. Having opened it sufficiently to separate the cut edges from each other, it will be found that the paper is equally divided into parts forming alternate external and re-entering angles, except at the two edges *bb*, where two external angles come together. Here the intervening portion of paper between the two contiguous external angles should be folded, by bringing the latter together, and creasing the paper down, so as to form a re-entering angle between them: this should be done at both places. Then opening the paper sufficiently to bring the bottom into proper shape, by thrusting out the part which is convex within, so as to make it project externally, the filter is completed, and being put into a funnel, is ready for use. Its appearance, when perfectly formed, is represented at fig. 11.

"It is necessary, in making these filters, that the folds be not continued to the point, but that they should stop about half an inch short of it; for if completed to the bottom, the frequent action of the fingers in folding will so far break down and destroy the texture of that part, that a hole probably will appear before the filter is finished; or if not, it will be so weakened as to be unable to bear a quantity of fluid without breaking. Hence that part of the filter will, during the folding, assume a concave form; and the regularity of the folds, which by practice may be easily attained, must be strictly attended to in the upper part, but may be dispensed with at the lower. When opened out, therefore, for the completion of that part, before the filter is put into the funnel, all that will be required is to push that side of the bottom outwards which is convex inwards, doing it so carefully as to cause no injury. The folds of the filter should be distinct and sharp, an effect which should be obtained by a single decisive pressure, and not by much fingering. No wrinkle or mark should appear in a well-made filter, except the folds described, and the portion of paper between the folds should be as stiff as when first taken up. The filter should be handled lightly during the whole of the operation, and never be opened out more than is represented in the last figure. It is best to keep the folds as close, and the whole filter as compact, as possible, dropping it loosely into the funnel, and permitting the fluid poured in to do the office of opening it out. It should be so regularly made, that when thus expanded by the fluid, the external angles of the folds should touch the glass at equal distances from each other, except at two opposite places where smaller divisions exist; and unless a large quantity of fluid be present, the angles at the upper part should remain nearly as sharp when the liquid is introduced as they were before. Below they gradually pass into the rounded surface, forming the centre or bottom of the filter, which will be about the size of a sixpence or shilling, according to the dimension of the funnel in that part. These filters leave such free space between themselves and the glass, as to admit of the passage of a far greater quantity of fluid than is necessary; and no obstruction being placed against the external surface of the paper, the whole acts in the filtration, and that in the most favourable manner.

"Of these two kinds of filters, which may be distinguished as the *plain* and the *folded*, sometimes the one and sometimes the other is preferable. When the object is to cleanse and purify the fluid, that being the valuable part, it is most rapidly and effectually attained by a folded filter; but when the precipitate is the part required to be taken care of, it is generally desirable not to spread it over the irregular and extensive surface of such a filter, but, by using a plain one, to retain it on a surface of only half the extent. It is then likewise of such uniform thickness in every part, as best to admit of the operation of washing by having successive portions of water passed through it, and when the filter is opened out, the precipitate is delivered in one continuous portion, and not divided into many parts, as happens with the folded filter.

"When a single filter is judged too weak to hold the mass of fluid it is required to sustain, a double one should be used. If the filter is to be a folded one, then a double thickness of paper is to be taken; but if plain filters are used, the two should be made separately, and put one into the other, in such a manner that the three thicknesses of the one may come against the single thickness of the other. Occasionally it is proper to strengthen the bottom of the filter, which, not being supported by the glass, has to support the greatest column of fluid; but not so as to obstruct the upper part, where a filtration as free as possible is required. In such a case a smaller filter is to be added to the exterior of the large one, so that it may not interfere with the precipitate within, when it is necessary to remove it from the paper.

"The filter and funnel being ready, and placed on the stand in one of the holes before mentioned, over a glass ready to receive the liquid, the mixture to be filtered is to be poured in. It should not be poured from a great height, nor upon the middle of the filter, but down the side, the force of its descent being diminished as much as possible by good management, lest it break a hole through the paper: for the same reason it is better to pour it down the rod. If the first portions of fluid which pass be not clear, they should be returned into the filter, and a second glass should be placed beneath. The solid matter in the liquid to be filtered will soon, by adhering to the paper, cause clear filtration, except perhaps in one or two particular cases, as with precipitated oxide of tin, &c. on which occasions a double thickness of paper must be used. On changing the vessels beneath the filter for the removal of the clear solution, it should be done so that no drop be lost. By inclining the empty vessel, its edge may be brought under the funnel before the full one is removed; and in no case should a vessel be left under the filter, in which there is not sufficient room for the contents of the latter if it should break. Such an accident ought not to occur, but ought always to be provided against.

"Sometimes hot filtrations are to be performed. Oils filter better hot than cold: tallow and cocoa-nut oil may be passed through paper when hot; and many solutions must be filtered at high temperatures, because of the greater solubility of the ingredients under those circumstances. In these cases the fluids should be heated in a flask or basin before they are poured into the filters, and the filter funnels being placed in the glasses or jars, and, after the fluid is poured in, covered over with a basin or glass plate, the whole should be enveloped in a piece of flannel or a dry cloth. If, from the length of the operation, or other causes, the flannel or cloth be not sufficient, it may be dispensed with; and the glass and filter being placed on a warm part of the sand-bath, should be covered with a box or vessel large enough to rest on the sand, and thus form a hot air-chamber for the process. When the operations are upon a small scale, a paper cone is sufficient to cover the vessels on the sand-bath, and keep them hot.

"When the object is hastily to filter a fluid for the purpose of removing pieces of dirt, then a little loose tow at the bottom of a funnel, or a piece of sponge slightly thrust in, is often sufficient for the purpose. Upon some few occasions filters for acids are required. These are generally recommended of powdered glass, being arranged somewhat in the manner described for lixiviation. Pieces of glass are put into the neck of the funnel; upon these smaller fragments, then again other layers of particles diminishing in size, until a moderately fine powder has been used, the top being finished with a layer of small fragments, to prevent disturbance by pouring. The pieces of glass should be well cleaned before pulverization, and, when arranged, some water should be passed through the filter, to remove alkali or other matters that may be separable from the glass, which should be that of wine-bottles, and not flint glass.

"Another mode of separating a fluid from the finely-divided solid matter it may contain, is to allow the latter to deposit, and then to remove the former. This is called *decantation*, and is a process much superior to filtration in many analytical experiments, and recommended in preference both by Lavoisier and Berzelius."

FIN, in *Natural History*, a well-known part of fishes, consisting of a membrane supported by rays, or little bony or cartilaginous ossicles.

FINAL, in general, whatever terminates or concludes a thing; as *final* judgment, *final* sentence, and the like.

FINAL *Cause*, is the end for which a thing is done. The final cause is the first thing in the intention of an agent, and the last in the execution.

FINAL Letters, among Hebrew grammarians, five letters so called, because they have a different figure at the end of words from that which they have in any other situation.

FINALE, a sea-port in the duchy of Genoa, and kingdom of Sardinia. It is divided into two parts, one called the Hill, the other the Marina. It is strongly fortified, especially against maritime attacks. The inhabitants amount to 3974, who carry on a brisk trade in olives and in oil, which the surrounding district copiously supplies.

FINANCES, in political economy, the revenues of a king or state; analogous to the treasury or exchequer of the English, and the *fiscus* of the Romans. The word is derived from the German *finantz*, scraping or usury; though Du Cange chuses rather to deduce it from the barbarous Latin *financia, prestatio pecuniaria*. See TAXATION.

FINCH, HENEAGE, first Earl of Nottingham, and Lord High Chancellor of England, was the son of Sir Heneage Finch, recorder of London, and born in December 1621. He received his education at Westminster school, and at Christ Church College, Oxford, of which he was a gentleman commoner; and he studied law in the Inner Temple, where, by his talents and diligence, he became remarkable for great legal acquirements. On the restoration of Charles II. he was made solicitor-general, and created a baronet. He was also appointed reader of the Inner Temple, and chose as his subject the statute of the 39th Elizabeth, concerning the payment and recovery of debts of the crown, which he treated with great force of reason and depth of legal erudition. As solicitor-general, he took an active part in the trials of the regicides; and, in 1661, he was chosen member of parliament for the university of Oxford, by the recommendation of Lord Clarendon; but, according to the author of *Athenæ Oxonienses*, he did his constituents no good, when they wanted his assistance for taking off the tax upon hearths. In 1665, after the prorogation of the parliament which then sat at Oxford, he was created doctor of civil law in full convocation; but after the ceremony had terminated, the public orator, being called upon to do his duty, stood up, and, in allusion to the tax above mentioned, observed, "that the university wished they had more colleges to entertain the parliament men, and more chambers, but by no means more chimneys;" an expression of academical opinion which, however undignified in itself, startled the new-made doctor of laws, who changed colour, and seemed by no means to relish the quaint remark of the orator. In 1667, when Lord Clarendon was impeached for certain alleged high crimes and misdemeanours, Sir Heneage, mindful of his old friend, stoutly defended him against the charges preferred by his enemies. In 1670 he was appointed attorney-general, and, some years afterwards, lord keeper. He was then raised to the peerage by the style and title of Baron Finch of Daventry, in the county of Northampton; and, in 1675, appointed lord high chancellor of England. He officiated as high steward at the trial of Lord Stafford, who, in the madness of that time, was found guilty of high treason by his peers, on a charge of being concerned in the Popish plot. In 1681 he was created Earl of Nottingham, and died, the following year, at his house in Queen Street, Lincoln's-Inn-Fields, from the exhaustion produced by long-continued exertion. Lord Nottingham was distinguished for both sagacity and eloquence; and though he lived in times when it was difficult to pursue a steady and consistent course, he conducted himself in such a manner as to retain the favour of the court without forfeiting the approbation of the people. "He was a person," says Mr Justice Blackstone, "of the greatest abilities, and most incorrupted integrity; a thorough master and zealous defender of the laws and constitution of his country; and endued with a pervading genius that enabled him to discover and pursue the true spirit of justice, notwithstanding the embarrassments raised by the narrow and technical notions which then prevailed in the courts of law, and the imperfect ideas of redress which had possessed the courts of equity. The reason and necessities of mankind arising from the great change in property, by the extension of trade, and the abolition of military tenures, co-operated in establishing his plan, and enabled him, in the course of nine years, to build a system of jurisprudence and jurisdiction upon wide and rational foundations, which have also been extended and improved by many great men who have since presided in Chancery; and from that time to this, the power and business of the court have increased to an amazing degree." In the name of the Earl of Nottingham have been published, 1. Several Speeches and Discourses on the trials of the Regicides; 2. Speeches delivered in both Houses of Parliament; 3. Speech at the Sentence of William Viscount Stafford, 7th December 1680; 4. Answers to his Majesty's command upon several Addresses presented to his Majesty at Hampton Court, 19th May 1681; 5. The Arguments upon which he made the Decree in the cause between the Honourable Charles Howard, plaintiff, Henry Duke of Norfolk, Henry Lord Mowbray his son, Henry Marquis of Dorchester, and Richard Marriot, Esq. defendants, folio; 6. An Argument on the claim of the Crown to pardon on Impeachment, folio. He also left in manuscript, *Chancery Reports*, and notes on Coke's *Institute*. (A.)

FINE, that which is pure and without mixture. The term is particularly used in speaking of gold or silver.

FINE, in *Law*, has different applications. Sometimes it is used for a formal conveyance of lands or tenements, or of any thing inheritable, being *in esse temporis finis*, in order to cut off all controversies. Others define it a final agreement between persons, concerning any lands, rents, or other subjects, of which any suit or writ is depending between them in any court.

FINE sometimes signifies a sum of money paid for entering lands or tenements let by lease; and sometimes a pecuniary mulct for an offence committed against the king and his laws, or against the lord of the manor.

FINE-Drawing, or *Rentering*, a dexterous sewing up or rejoining the parts of any cloth, stuff, or the like, torn or rent in the dressing, wearing, or otherwise.

FINE-Stiller, in the distillery. That branch of the art which is employed in distilling spirit from treacle or other preparations or recrements of sugar, is called *fine-stilling*, by way of distinction from malt-stilling; and the person who exercises this part of the trade is called a *fine-stiller*.

FINERS *of* GOLD *and* SILVER are those who purify and separate these metals from other coarser ones, or their ores, by means of fire and acids. They are also called *parters* in our old law books, and sometimes *departers*.

FINEERING. See VENEERING.

FINGAL, king of Morven, in ancient Caledonia. See OSSIAN.

FINKENWERDER, an island in the river Elbe, belonging to the kingdom of Hanover, in the bailiwick of Harburg, and between that city and Hamburg. It is fertile, and contains a small town of the same name, with 560

Finisterre || Finland.

inhabitants, who furnish the market of both cities with fruits and vegetables.

FINISTERRE, a maritime department of France. It is bounded by the sea on three sides, and on the east by the departments of the Côte du Nord and of Morbihan. It is in the shape of a triangle, and extends over 2890 square miles, or, according to the Almanac-Royal, 693,384 hectares, of which 252,704 are under the plough, 106,281 are in fallow, 23,389 are pasturel and, 148,364 are woods, 35,868 are waste, 56,414 are covered with lakes and estuaries, 22,267 are the beds of rivers and harbours, and the remainder roads, and the sites of cities, towns, and villages. The surface is very unequal, consisting of chains of hills running through the peninsula, some reaching the height of 1000 feet, with valleys between them of various extent.

The civil divisions are into five arrondissements, forty-three cantons, and 287 communes, inhabited by 452,450 persons. The inhabitants are a distinct race from the French, and mostly speak the old language of the Breyzards, the name by which they are distinguished. They are obstinate in their adherence to old and antipathy to new customs. Their clothing is little altered in the last thousand years, which in form and colour varies in each place, thus showing the dwelling of each person. There are whole communes in which no individuals are to be found who can read or write. They live either in scattered houses or small hamlets, and more than 25,000 houses are so wretched in appearance when seen, that they resemble the huts of savages. They are mostly hidden behind hedges and banks, and only visible by the smoke which issues from the doors, for they have neither chimneys nor windows. The cattle and the families live together in a state of disgusting filth. The females, who are commonly very ugly, are oppressed by their labour, and so contemptuously treated that they are not even suffered to eat with the men.

With all this they are said to be hospitable, upright, brave, and patriotic, and content with their barley bread, milk, and (but of late years) potatoes. The agriculture is in a backward state, and produces less corn than is required for the consumption; and since the population has increased, severe scarcity would be annually felt but for the introduction of potatoes, which are now extensively cultivated. The sheep, cows, and especially the horses, are diminutive; but the swine are fine and numerous.

The inhabitants of the towns in general are more like the other parts of the French nation. Those on the coast pursue the fisheries with success, especially that for sardinias. The only mines are those of lead, in which silver is found mixed with that metal. In two mines, at Poullalouen and Huelgoet, 900 workmen are employed, who raise yearly 600 tons of lead, and from it extract 26,000 ounces of silver.

In some parts, especially at Morlaix, there are some manufactories of linen, sail-cloth, twine, cordage, and paper. At that port also the surplus productions of the soil are exported to other portions of the kingdom, as well as to foreign parts.

FINLAND, a province formerly of Sweden, but at present under the dominion of Russia, of which it is called a stadtholdership. It extends from 19. 35. to 33. 1. east longitude, and from 59. 50. to 69. 55. north latitude; and, including Lappmark, extends over the vast space of 140,844 square miles, although the inhabitants in the year 1814 amounted to no more than 1,460,000. The country is generally hilly rather than mountainous, as none of the elevations exceed 3500 feet, and the highest are only in the north and in the west parts. In the east it is filled with sand hills, rocks, woods, marshes, lakes, and rivers; but between the hills are some spots, either cultivated, or affording natural pasture. On the sea shore, both in the Gulf of Bothnia and in that of Finland, the rocks and sands, and the small islands and shores, are so numerous as to render the navigation highly dangerous.

The climate, though varying with the degrees of latitude, is unfavourable to a great population, from the excessive cold of the long winter, and the excessive heat and aridity of the short summer. Yet, when under the Swedish government, Finland not only produced sufficient corn, chiefly rye, for its own consumption, but supplied a part of the demand of the metropolitan provinces. Of late the culture of potatoes has been extended. Finland produces hemp and flax; the former inferior in quality to the latter. The chief articles of export are the productions of the forest, which supply fuel to Stockholm, and masts and ship-timber to other countries. Considerable quantities of pot and pearl ashes, of pitch and tar, are also exported, and some salted fishes; but salt is a scarce commodity, and the want of it is felt by others as well as by the fishermen. The inhabitants being of different races, speak dialects of the Finnish, Lappish, and Swedish languages, whose origin being the same, are understood without much difficulty. The whole adhere to the Lutheran confession, except in some of the southern parts, where the Greek church has adherents among those of the Russian nation.

Since Russia possessed the country, the administration of that empire has been in part introduced, but with much deference to the ancient customs and laws of the inhabitants. The province is now divided into twelve circles.

FIRE, NATURE OF. See the article HEAT.

Wild FIRE, or *Greek-FIRE*, a kind of artificial or factitious fire, which burns even under water, and that with greater violence than out of it. It is composed of sulphur, naphtha, pitch, gum, and bitumen; and is only extinguishable by vinegar mixed with sand and urine, or by means of raw hides.

The motion or tendency of this fire is said to be contrary to that of natural fire, and always follows the direction in which it is thrown, whether it be downwards, sidewise, or otherwise. The French call it *Greek fire*, or *feu Grequois*, because it was first used by the Greeks, about the year 660; as is observed by Petavius, on the authority of Nicetas, Theophanes, Cedrenus, and others.

The inventor, according to the same authority, was an engineer of Heliopolis, in Syria, named Callinicus, who first applied it in the sea-fight in which Constantine Pogonates commanded against the Saracens, near Cyzicus, in the Hellespont; and with such effect, that he therewith burnt the whole fleet, in which were thirty thousand men. But others think it of much older date, and consider Marcus Gracchus as the inventor; an opinion which is supported by several passages both in the Greek and Roman writers, showing it to have been anciently used by both these nations in their wars. Constantine's successors used it on different occasions with equal advantage; and, what is remarkable, they were fortunate enough to keep the secret of the composition to themselves, so that in the year 960 no other nation was acquainted with the composition.

Hugh, king of Burgundy, having demanded ships of the Emperor Leo, for the siege of Fresne, desired likewise that they should be provided with the Greek fire.

Father Daniel gives a good description of the Greek fire, in his account of the siege of Damietta undertaken by St Louis. Every body, says that author, was astonished at the Greek fire, which the Turks then prepared, and the secret of which is now lost. They threw it out of a kind of mortar; and sometimes shot it with an odd sort of cross-bow, which was strongly bent by means of a handle or winch, and of much greater force than the mere arm. That thrown with the mortar sometimes appeared in the air of the size of a tun, with a long tail, and a noise like that of thunder. The French by degrees discovered the secret of extinguishing it, in which they several times succeeded.

Balls of FIRE, in *Meteorology*, are luminous bodies, which appear at a considerable height above the earth, shining occasionally with very great splendour, and sometimes leaving a luminous track behind them after they have disappeared. The larger ones in this hemisphere proceed generally from north to south with great velocity, frequently exploding into globes of smaller size, and sometimes vanishing with a report, sometimes without one. They are not unfrequently attended with a discharge of solid compounds of earthy and metallic matters, called meteoric stones, the descent of which, though stubbornly denied for a time, was finally established about the beginning of this century.

These luminous appearances no doubt constituted part of the ancient prodigies, blazing stars or comets, which last they sometimes resemble in being attended with a train; but they frequently appear with a round and well-defined disk. The first of these of which we have any accurate account, was observed by Dr Halley and some other philosophers at different places, in the year 1719. From the slight observations they could take of its course, the perpendicular height of this body was computed at about seventy miles above the surface of the earth. The height of others has also been computed, and found to vary from thirty-three to a hundred miles. The velocity at which they travel is estimated at from five to thirty-three miles in a second. The most remarkable of these on record appeared on the 18th of August 1783, about nine o'clock in the evening. It was seen to the northward of Zetland, and took a southerly direction for an immense space, being observed in the southern provinces of France, and, according to one account, in the ecclesiastical capital of Italy. During its course it frequently changed its shape; sometimes appearing in the form of one ball, sometimes of two or more, sometimes with a train, sometimes without one. It passed over Edinburgh nearly in its zenith, and had then the appearance of a well-defined round body, extremely luminous, and of a greenish colour, the light which it diffused on the ground giving likewise a greenish cast to objects. After passing the zenith it was attended by a train of considerable length, which continually augmented, and at last entirely obliterated the head, so that it looked like a wedge, flying with the obtuse end foremost. The motion was not apparently rapid, by reason of its great height; though in reality it must have moved with great velocity, on account of the immense space over which it travelled in a short time. In other places its appearance was very different. At Greenwich we are told that "two bright balls parallel to each other led the way, the diameter of which appeared to be about two feet; and were followed by an expulsion of eight others, not elliptical, seeming gradually to mutilate, for the last was small. Between each two balls a luminous serrated body extended, and at the last a blaze issued which terminated in a point. Minute particles dilated from the whole. The balls were tinted first by a pure bright light, then followed a tender yellow, mixed with azure, red, and green; which, with a coalition of bolder tints, and a reflection from the other balls, gave the most beautiful rotundity and variation of colours that the human eye could be charmed with. The sudden illumination of the atmosphere, and the form and singular transition of this bright luminary, tended much to make it awful; nevertheless, the amazing vivid appearance of the different balls, and other rich connective parts not very easy to delineate, gave an effect equal to the rainbow in the full zenith of its glory."

Dr Blagden, in a paper on the subject inserted in the seventy-fourth volume of the *Philosophical Transactions*, not only gave a particular account of this and other meteors of the kind, but offered several conjectures as to the probable causes of them. The first thing which occurred to philosophers on this subject was, that the meteors in question were burning bodies rising from the surface of the earth, and flying along the atmosphere with great rapidity. But this hypothesis was soon abandoned, on considering that there was no power known by which such bodies could either be raised to a sufficient height, or projected with the velocity of these meteors. The next hypothesis was, that they did not consist of one single body, but of a train of inflammable vapours, extending a vast way through the atmosphere, which being kindled at one end, displayed the luminous appearances in question by the fire running from one end of the train to the other. To this hypothesis, which was invented by Dr Halley, Dr Blagden objected that no just explanation was given of the nature of the vapours themselves, the manner in which they were raised up, or their regular arrangement in straight lines of such vast extent; or how they could be supposed to burn in such rarefied air. "Indeed," says he, "it is very difficult to conceive how vapours could be prevented, in those regions where there is in a manner no pressure, from spreading out on all sides in consequence of their natural elasticity, and instantly losing that degree of density which seems necessary for inflammation. Besides, it is to be expected, that such trains would sometimes take fire in the middle, and thus present the phenomenon of two meteors at the same time, receding from one another in a direct line."

For these and other reasons the hypothesis of Dr Halley was abandoned, and another substituted in its place. This was, that the meteors in question are permanent solid bodies, not rising from the earth, but revolving round it in very eccentric orbits, and thus in their perigeon moving with inconceivable rapidity. But this hypothesis is likewise objectionable. Another theory supposes that the meteors in question are a kind of bodies which take fire as soon as they come within the atmosphere of the earth. Sir Humphry Davy's discovery that the earths and alkalis are metallic oxides, affords some plausibility to this theory, especially in cases where the meteors are accompanied with the descent of solid bodies to the earth. It has been suggested that the bases of the earth may exist in the meteor in a metallic state, and that when the body arrives within the range of our atmosphere, the strong affinity which it is well known these metallic bases have for oxygen, causes them to unite and produce violent combustion. The origin of fire-balls has also been ascribed to the agency of electricity, and there seems little doubt that this is really the true way of accounting for them.

Falling or *shooting stars* are the same phenomena upon a smaller scale. They are to be seen at all seasons, but most frequently during the prevalence of the northern lights, and most commonly in the lower regions of the atmosphere. The cause of these phenomena, as of those of a more magnificent description, has been attributed to electricity. This theory, however, was objected to by Sir Humphry Davy; and his opinions on every subject are entitled to the highest deference, and to deliberate consideration. He conceived them to be attributable to falling stones. But the subject of meteoric stones, including fire-balls and other meteors, will be treated of under METEOROLOGY. It may also be mentioned, that Chladni, in his work on Fiery Meteors (Vienna, 1819), considers them as solid bodies, formed above the region of our atmosphere, and classes them with aerolites or meteoric stones. See METEOROLOGY.

FIRE-Engine. See STEAM-ENGINE.

FIRE-Escapes. See LIFE-PRESERVERS.

FIRE-Flies. See *Elator*, *Lampyris*, and *Fulgora*, in the Index to ENTOMOLOGY.

FIRE-Philosophers, or *Philosophi per Ignem*, a fanatical sect of philosophers who appeared towards the close of the sixteenth century, and made a figure in almost all the countries of Europe. The distinguishing tenet from which they derived this appellation was, that the intimate essences of natural things were only to be known by the trying efforts of fire, directed in a chemical process. They were also called Theosophists, from their declaring against human reason as a dangerous and deceitful guide, and representing a divine and supernatural illumination as the only means of arriving at truth; and Paracelsists, from Paracelsus, the eminent physician and chemist, who was the chief ornament of this extraordinary sect. It was patronized in England by Robert Flood or Fludd, who endeavoured to illustrate the philosophy of Paracelsus in a great number of treatises; in France it was zealously propagated by Rivier; in Denmark, by Severinus; in Germany, by Kunrath, an eminent physician of Dresden; and in other countries by ardent votaries, who assumed an air of piety and devotion, and proposed to themselves no other end than the advancement of the divine glory, and the restoration of peace and concord in a divided church. One of the most celebrated of these was Daniel Hoffman, professor of divinity in the university of Helmstadt, who, availing himself of some unguarded passages in the writings of Luther, maintained that philosophy was the mortal enemy of religion; that truth was divisible into two branches, the philosophical and theological; and that what was true in philosophy was false in theology. But Hoffman was afterwards obliged, by the interposition of Henry Julius, duke of Brunswick, to retract his invectives against philosophy, and to acknowledge in the most open manner the harmony of sound philosophy with genuine theology.

FIRE-Place. See FURNACE.

FIRE-Ship, or *Brulot*, a vessel filled with combustible materials, and fitted with grappling irons, to hook and set fire to hostile ships.

FIRKIN, an English measure of capacity for liquids, being the fourth part of the barrel, and containing eight gallons of ale, soap, or herrings, and nine gallons of beer, old measure. Imperial measure contains one sixtieth part less in the gallon. See WEIGHTS AND MEASURES.

FIRLOT, a dry measure used in Scotland. The wheat firlot contains $21\frac{1}{4}$ pints of that country, or about 2214 cubic inches; and the barley firlot, 31 standard pints, or 3232 cubic inches. Hence the Scotch wheat firlot exceeds the old English bushel by 33 cubic inches, and the imperial bushel by 4 cubic inches.

FIRMAMENT, in the ancient astronomy, the eighth heaven or sphere, in which the fixed stars were supposed to be placed. It is called the eighth, with respect to the seven heavens or spheres of the planets which it surrounds.

The firmament is supposed to have two motions; a diurnal motion, given to it by the *primum mobile*, from east to west, about the poles of the ecliptic; and another opposite motion from west to east; which it completes, according to Tycho, in 25,412 years; according to Ptolemy, in 36,000; and according to Copernicus, in 258,000; when the fixed stars return to the same precise points in which they were at the commencement of this grand revolution. This period is commonly called the Platonic or great year.

FIRMAN is a passport granted to travellers and others in the dominions of Turkey, and usually bearing the signet of the grand signior himself.

FIRMICUS, MATERNUS JULIUS, a Latin writer who flourished under the successors of Constantine. About the year 345 he composed a work entitled *De Erroribus Profanarum Religionum*, which he inscribed to Constantius and Constans, the sons of Constantine, and which is happily still extant, accompanied with the annotations of John Wouver. To Firmicus are also attributed eight books on astronomy, first printed by Aldus Manutius in 1501, and reprinted several times since; but as this work contains nothing relating to the true science of astronomy, and is filled with astrological calculations, after the manner of the Babylonians and Egyptians, Baronius doubts whether a good and pious Christian, as Firmicus is represented to have been, could have indulged in such profane and impious speculations. Cave, however, supposes that he might have written these books anterior to the date of his conversion from Paganism; a supposition not incompatible with the opinion of Baronius. Of the treatise on the *Errors of the Profane Religions*, the principal editions subsequent to that of Aldus are, one printed at Strasburg in 1562, another at Heidelberg in 1599, and a third at Paris in 1610, all in 8vo; but afterwards it was conjoined with Minucius Felix, and printed at Amsterdam in 1645, at Leyden in 1652, and again at Leyden by James Gronovius, in 1709, 8vo. It is likewise to be found in the *Bibliotheca Patrum*, and at the end of Cyprian, printed at Paris in 1666. (Dupin; Cave; Moreri; Fabricius, *Bibl. Lat.* and *Bibl. Lat. Med.*) (A.)

FIRST-BORN. (See PRIMOGENITURE.) In Scripture the term first-born is often used in a figurative sense, to signify that which is first, most excellent, or most distinguished in any thing. Thus it is said of Christ that he is "the first-born of every creature;" and in Revelation he is called "the first-begotten of the dead," that is, according to the commentators, begotten of the Father before any creature was produced, and the first who rose from the dead by his own power. "The first-born of the poor" signifies the most miserable of all the poor; and in Job, "the first-born of death" means the most terrible of all deaths.

FIRST Fruits (*primitiæ*), amongst the Hebrews, oblations to God of part of the fruits of the harvest, as an acknowledgment of his sovereign dominion. The first of these fruits was offered in the name of the whole nation, being either two loaves of bread, or a sheaf of barley which was thrashed in the court of the temple. Every private person was obliged to bring to the temple his first fruits, consisting of wheat, barley, grapes, figs, apricots, olives, and dates.

There was another kind of first fruits offered to God. When bread was kneaded in a family, a portion of it was set apart and given to the priest or Levite who dwelt in the place; but if there was no priest or Levite there, it was cast into the oven, and consumed by the fire. These offerings constituted a considerable part of the revenues of the Hebrew priesthood.

FIRST Fruits are frequently mentioned by ancient Christian writers as forming part of the church revenue. One of the councils of Carthage enjoins that they should consist only of grapes and corn; which shows that this was the practice of the African church.

FIRST Fruits, in the Church of England, are the profits of every spiritual benefice for the first year, according to the valuation thereof entered in the king's books.

FISC (*Fiscus*), in the *Civil Law*, the treasury of a prince or state, or that into which all things due to the public fall to be paid or delivered. The word is derived from the Greek φισκος, *a great basket*, used when they went to market. By the civil law, none but a sovereign prince has a right to have a fisc or public treasury. At Rome, under the emperors, the term *ærarium* was used for the revenues destined to support the charges of the empire;

the *fiscus* for those of the emperor's own family. The treasury, in fact, belonged to the people, and the *fiscus* to the prince. Hence the goods of condemned persons, if appropriated to the use of the public, were said *publicari;* if to the support of the emperor or prince, *confiscari.*

FISCAL, in the *Civil Law*, something relating to the pecuniary interest of the prince or people. The officers appointed for the management of the fisc were called *procuratores fisci*, and *advocati fisci;* and among the cases enumerated in the constitutions of the empire, where it was their business to plead, one is against those who have been condemned to pay a fine to the fisc on account of their litigiousness, or frivolous appeals to the courts of law.

FISH. See Ichthyology.

Fishes, in *Heraldry*, are the emblems of silence and watchfulness, and are borne upright, imbowed, extended, endorsed respecting each other, surmounting one another, fretted, and so on.

In blazoning fishes, those borne feeding should be deemed *devouring;* all fishes borne upright and having fins, should be blazoned *hauriant;* and those borne transverse the escutcheon, should be termed *naiant.*

Fish Ponds, excavations filled with water, and intended for the breeding or feeding of fish. In making a pond, its head should be at the lowest part of the ground, that the trench of the flood-gate or sluice, having a good fall, may not be too long in emptying. The best way of making the head secure is to drive in two or three rows of stakes about six feet long, at the distance of about four feet from each other, the whole length of the pond head, the first row of which should be rammed at least about four feet deep. If the bottom is false, the foundation may be laid with quicklime; which, when slaked, will render it as hard as a stone. Some place a layer of lime, and another of earth dug out of the pond, among the piles and stakes; and when these are well covered, drive in others as they see occasion, ramming the earth as before, till the pond head be of the height which is required.

The dam should be made sloping on each side, leaving a waste to carry off the superabundant water in times of floods or rains; and as to the depth of the pond, the deepest part need not exceed six feet, rising gradually in shoals towards the sides, for the fish to sun themselves, and lay their spawn. Gravelly and sandy bottoms, especially the latter, are best for breeding; and a fat soil with a white fat water, as the washings of hills, commons, streets, sinks, and the like, is best fitted for fattening all sorts of fish. For storing a pond, carp is to be preferred for its goodness, quick growth, and great increase, as breeding five or six times a year. A pond of an acre, if it be a feeding and not a breeding one, will every year feed two hundred carps of three years old, three hundred of two years old, and four hundred of a year old. Carps delight in ponds which have marl or clay bottoms, with plenty of weeds and grass, on which they feed in the hot months.

Ponds should be drained every three or four years, and the fish sorted. In breeding ones, the smaller fishes are to be taken out, to store other ponds withal; leaving a good stock of females, at least eight or nine years old, as they never breed before that age. In feeding-ponds, it is best to keep them pretty near of a size.

FISHER, John, Bishop of Rochester, was born at Beverley, in Yorkshire, in the year 1459, and educated in the collegiate church of that place. In 1484, he removed to Michael House in Cambridge, of which college he was elected master in the year 1495. Having applied himself to the study of divinity, he took orders; and becoming eminent as a divine, attracted the notice of Margaret, countess of Richmond, mother of Henry VII., who appointed him her chaplain and confessor. In 1501 he took the degree of doctor in divinity, and the same year was elected chancellor of the university. In the year following he was appointed Lady Margaret's first professor of divinity in Cambridge; and in 1504 he was consecrated bishop of Rochester, a see which he would never resign, though he was offered both Ely and Lincoln. It is generally known that the foundation of the two colleges of Christ-Church and St John's, Cambridge, was owing to Bishop Fisher's persuasion and influence with the Countess of Richmond; he not only formed the design, but superintended the execution, and was appointed by the statutes visitor for life after the death of Lady Margaret. On the promulgation of Luther's doctrine, the bishop was the first to enter the lists against him. Upon this occasion he exerted all his influence, and is generally supposed to have written the book on account of which Henry VIII. obtained the title of *Defender of the Faith.* Hitherto he had continued in favour with the king; but in 1527, having opposed his divorce, and denied his supremacy, the implacable Harry determined, and finally effected, his destruction. In 1533 the parliament found him guilty of misprision of treason, for concealing certain prophetic speeches of a fanatical impostor, Elizabeth Barton, otherwise called the Holy Maid of Kent, relative to the king's death, and condemned him, with five others, to suffer loss of goods and imprisonment during his majesty's pleasure; but he was subsequently released, upon paying a fine of L.300 for the king's use.

King Henry having now espoused Anne Boleyn, his obsequious parliament took the oath of allegiance proper for the occasion. But in this oath the Bishop of Rochester steadily refused to join, alleging that his conscience had not been convinced that the king's first marriage was against the law of God. For this refusal he was attainted by the parliament of 1534, and committed to the Tower, where he experienced cruel treatment, and would probably have died a natural death, had not the pope created him a cardinal. The king, having now determined on his destruction, sent Rich the solicitor-general, under the pretence of consulting the bishop upon a case of conscience, but really with a design to draw him into a conversation concerning the supremacy. The honest old bishop spoke his mind without suspicion or reserve; and an indictment and conviction of high treason were the consequence. He was beheaded at Tower Hill on the 22d of June 1535, in the seventy-seventh year of his age. Thus died this veteran prelate, who, notwithstanding his inflexible enmity to the Reformation, was undoubtedly a learned, pious, and honest man.

The Bishop of Rochester was the author of a number of works, of which the following is a list: 1. *Assertionum Martini Lutheri Confutatio;* 2. *Defensio Assertionis Henrici Octavi de Septem Sacramentis;* 3. *Epistola Responsaria Epistolæ Lutheri;* 4. *Sacerdotii Defensio contra Lutherum;* 5. *Pro Damnatione Lutheri;* 6. *De Veritate Corporis et Sanguinis Christi in Eucharistia, adversus Œcompoladium;* 7. *De Unica Magdalena;* 8. *Petrum fuisse Romæ;* 9. Several Sermons, amongst which was one preached at the funeral of Henry VII., and another at that of the Countess of Richmond; 10. His opinion of King Henry the Eighth's marriage, in a letter to T. Wolsey, printed at the end of the second volume of Collier's *Ecclesiastical History.* Most of the tracts above mentioned were collected and printed in one volume folio, at Wurtzburg in 1595. Fisher, as already stated, is supposed to have had a considerable share in the composition of Henry's book, entitled *Assertio septem Sacramentorum;* and in the Norfolk library of manuscripts belonging to the Royal Society there is an answer made by him to a book printed at London in 1530, concerning Henry's marriage with Queen Catherine.

FISHERIES.

We propose in the present article to take a general and extended view of this important branch of employment, and at the same time to give a sketch of the present state both of the home and foreign fisheries.

HOME FISHERIES.

Alleged neglect of by Great Britain.

The alleged neglect of the fisheries, on the part of Great Britain, has been the subject of unqualified censure from a very early period of her naval and maritime history; and reproaches have been dealt out with no sparing hand, not only for having disregarded those advantages so liberally bestowed by nature along the extensive coasts of her sea-girt islands, in supplying a wholesome and nutritious article of food for the sustenance of an abundant population, but also for suffering the nations of the Continent to resort to her very bays and harbours without molestation, and even purchasing from them that very property which she was either too ignorant or too indolent to procure by her own sagacity or industry, though neither of these required to be exerted in any extraordinary degree in the pursuit of this occupation. "The fishery," says Sir William Monson, "needs no discovery; the experience of our neighbours having found it out, and practised it since the year 1307, to their immeasurable wealth and our shame."

Contrasted with the attention of the Dutch.

Thus also Sir John Boroughs complains in his *Sovereignty of the British Seas*, that "it maketh much to the ignominy and shame of our English nation, that God and nature offering us so great a treasure, even at our own doors, we do, notwithstanding, neglect the benefit thereof, and, by paying money to strangers for fish of our own seas, impoverish ourselves to make them rich;" and as a contrast to our supposed indolence and indifference, he draws a lively picture of the bustle and activity which the herring fishery of Holland communicated to the various tradesmen and artificers, labourers, salters, packers, and others, and of the multitude of poor women and children to whom it afforded employment. In a little pamphlet entitled *England's Path to Wealth and Honour*, the whole alphabet in regular order is ingeniously brought to bear, in the shape of a dialogue between an Englishman and a Dutchman, on the trades and occupations connected with the herring fishery of Holland. The importance, indeed, of this branch of national industry in that country is pretty obvious from the following abstract of the population of the States-General taken in 1669.

Persons employed as fishermen, and in equipping fishermen with their ships, boats, tackle, conveying of salt, &c.	450,000
Persons employed in the navigation of ships in the foreign trade, wholly independent of the trade connected with the fisheries	250,000
Persons employed as manufacturers, shipwrights, handicraft trades, dealers in those manufactures	650,000
Persons employed in agriculture, inland fishing, daily labourers	200,000
Inhabitants in general not included in any of the above	650,000
Idle gentry without calling, statesmen, officers, soldiers, beggars, &c. supported by the labour of the rest	200,000
Making a total of	2400,000

From which it appears that the pensionary De Witt did not exaggerate when he stated that every fifth man earned his subsistence by the sea fishery; that Holland derived her main support from it; and that the herring fishery ought to be considered as the right arm of the republic. It is further asserted that, when in the zenith of her prosperity, not less than 3000 boats, of various kinds, were employed in the bays and islets of her own coasts; and that, in those of Great Britain, they had 800 vessels, from sixty to a hundred and fifty tons burden, occupied generally in the cod and ling fishery, besides others employed in carrying out salt to them, and returning with cured fish; that from Buchan-ness to the mouth of the Thames they had a fleet of 1600 busses actively engaged in the herring fishery, each of which might be said to give employment to three others in the importation of foreign salt, in carrying the salt to fishing ships and returning with cured fish, and in the exportation of that fish to a foreign market; thus making the total number of shipping engaged in and connected with the herring fishery alone to amount to 6400 vessels, calculated to give employment to 112,000 mariners and fishermen. By the same authority we are told that Holland, at that time, could boast of 10,000 sail of shipping and 168,000 mariners; "although the country itself affords them neither materials, nor victual, nor merchandise, to be accounted of towards their setting forth." Indeed the Dutch themselves made no scruple of avowing that the wealth, strength, and prosperity of the United Provinces were derived from the herring fishery; the importance of which was strongly marked by an observation in common use among them, that "the foundation of Amsterdam was laid on herring-bones."

No wonder, then, that the example of the Dutch should be held forth as a reproach to England; and we find, accordingly, that it was so considered by some of the ablest writers of former times, as Sir Walter Raleigh, Sir William Monson, Sir William Petty, Sir Roger L'Estrange, and others. It would seem, however, to have altogether escaped these writers, that the situation and circumstances of the Dutch were entirely different from those in which the people of the British islands were placed. The provinces of Holland where the fisheries flourished had few or no resources but those which the waters afforded them, they grew no corn, they had no superabundance of food for the rearing of cattle, they had few or no manufactures; whereas Great Britain had all these, and abounded in most of them. The Dutch having, therefore, neither food nor raiment but what they must purchase from foreign nations, and the only article they had to offer in return being the products of the seas, it was necessary for them to expend their whole industry in availing themselves of those products, in order to exchange them for others of the land. It was not therefore from choice, but absolute necessity, that the Hollanders braved the dangers and submitted to the fatigues of the deep-sea fishery. It was their whole resource, and afforded them the only scope for turning their industry to profit; and it must be allowed that, by an extraordinary degree of patience and perseverance, and by long practice, they succeeded in bringing to a state of unrivalled perfection the mode of catching and the method of cure, which other nations, less experienced and less interested, had not arrived at; though it is now known and admitted that there is no great art or mystery in the craft, nothing that British fishermen could not then have, and, in point of fact, nothing which they have not of late years accomplished in as perfect a manner as the Dutch.

land.

But the case was different with regard to Great Britain. That country laboured under none of the disadvantages, Encou-rageme given t the fish ries.

and felt none of the necessities, which pressed upon Holland. Her capital was employed in foreign commerce, in the improvement of her agriculture, and in the introduction of some and the perfection of other branches of manufacture. The complaints, therefore, of the indolence of the British, of their buying fish from the Dutch rather than choosing to undergo the risk and fatigue of catching them, even on their own shores, will not perhaps, on due consideration, appear to be well founded. Their conduct may be ascribed rather to the very natural result of being able to employ their capital in more lucrative, more pleasing, and less precarious investments. It would be too much to expect that he who can buy a fish for half the money required to catch one, will quit his present employment and turn fisherman; or that he who can make a greater and more certain profit in commerce, agriculture, or manufactures, than by fishing, will divert his capital from the former to embark in the latter. The government had repeatedly held out encouragement for the pursuit of the fisheries, and aided the efforts of individuals in various ways to promote the success of a branch of national industry of so much importance to the national wealth and strength. Liberal subscriptions for this purpose have, at various times, been set on foot; privileges and immunities have been granted; villages have been built at the public expense, and ships and boats with all the necessary articles and tackle supplied; premiums have been conferred, bounties granted, duties exempted; the fishermen have been protected from the impress, and those who may have followed the occupation for seven years allowed to set up, and freely exercise any trade or profession in any town or place of Great Britain.

The failure, therefore, could not always have been owing to want of protection and encouragement, though it may, in some measure, be owing to the want of knowledge or circumspection in the way of administering it. Neither could it be ascribed to the want of funds. In 1580 a plan was matured for raising L.80,000 for establishing the British fishery. In 1615 the same sum was raised by a joint-stock company. In 1632 a royal fishing company was established by the sanction of King Charles I., who, in order to increase the demand, prohibited the importation of foreign fish, directed a supply to be furnished for his fleet, and ordered lent to be more strictly observed. In 1660 parliament granted a remission of the salt duties, and freed all the materials employed in the fisheries from customs and excise. In 1661 the national fishery met with very great encouragement under the auspices of Charles II. In 1677 this monarch incorporated the Duke of York and others into "The Company of the Royal Fishery of England;" but on this occasion the miserable capital was exhausted in the purchase and fitting out of a few busses, built in Holland, and manned with Dutchmen, which were seized by the French on the breaking out of the war. In 1713 it was proposed to raise L.180,000 on annuities, for the purpose of establishing a fishing company. In 1749, by the recommendation of George II. in his opening speech to parliament, and in consequence of a report of a committee of the House of Commons, the sum of L.500,000 was subscribed for carrying on the fisheries, under a corporation, by the name of "The Society of the Free British Fishery," of which the Prince of Wales was chosen governor. This society, patronized by men of the first rank in the kingdom, promised fair for a little time, but soon began to languish; nor was the large bounty of 56s. a ton able to prevent its total failure. The attention of parliament was again called to this great national object in 1786, when a new corporation was formed, under the name of "The British Society for Extending the Fisheries and Improving the Sea Coasts of the Kingdom," which has continued, with various modifications, to the present time; and, as we shall presently see, has of late years been in a flourishing and progressive state of improvement.

Present impediments to the progress of the fisheries exaggerated.

Thus, then, it is evident that we must seek for the real grounds of the general languishing state of the British fisheries in other causes than those which have usually been assigned by our ancestors; and though the complaint in modern times may have some foundation, which is almost exclusively levelled against the salt duties, and, after these were wholly removed, against the numerous checks and excise regulations, which are stated to be as grievous and discouraging as were the duties themselves; yet the impediments which these are alleged to throw in the way of the improving state of the fisheries have probably been much exaggerated. There can be no doubt that much benefit would be derived from a total repeal of all the acts relating to the duties and the regulations of salt; and yet, when the old writers stated their grievances, the article of salt is never once mentioned. In fact there were then neither duties nor restrictions on this article of universal use; and yet the fisheries did not flourish under the free and unlimited use of it.

The salt laws were supposed to operate strongly against the prosecution of the fisheries, and this was stated as one of the reasons which produced their repeal; but they scarcely affected those fisheries which were established and conducted on a grand scale. What then, it may be asked, is the real cause of our fisheries not being carried on to a greater extent, at a time when population is so rapidly increasing, and work not to be found for multitudes of the labouring classes of the community? It certainly is not that the government is indifferent or insensible to the political importance of the fisheries. It has not only at different times held out such encouragements as were deemed conducive to the end in view, but shown itself so jealous of the interference of our neighbours as to attempt to establish an appropriate and exclusive fishery in all the seas surrounding our coasts. Thus James I. in 1600 issued a proclamation prohibiting all persons, of what nation or quality soever, not being natural born subjects, from fishing upon any of the coasts and seas of Great Britain and Ireland, and the isles adjacent, without first obtaining licenses from the king. But this, as well as the repetition of the prohibition by Charles I. in 1636, was utterly disregarded by the continental powers. To enforce this measure, the Duke of Northumberland, as admiral of the fleet, was sent into the North Sea to compel the Dutch fishermen to take licenses, and pay for the same; but the ambassador of the States-General in England remonstrated against so unprecedented a proceeding, and disavowed the acts of their fishermen.

The attempt to set up a limited fishery, and to prescribe boundaries to the prohibited grounds, met with no better success; but they showed at least a desire to prevent the advantages derivable from this element from falling into the hands of others. It is probable, however, that these claims were set up with the view rather of maintaining the title of the sovereignty of the seas, than from any contemplation of the national advantages derivable from the encouragement of the fisheries; and more especially for the purpose of preventing any encroachments on the part of the Dutch and French.

This, however, has been found to be impossible. The Dutch continue to fish even into the mouths of the Thames, and the French insist on their right to fish within a mile of the English coast, whilst they also claim the right of excluding our fishermen within a league of their own shores, and in some places three leagues; and it is contended by jurists, that as the fisheries on the sea are common to all mankind, no fixed laws can be made by any nation to the exclusion of any other, and that whatever rights or restrictions now exist, are sanctioned by prescriptive usage, and can only be altered by treaties or conventions between the parties who may mutually agree to a change.

Real cause of the backward state of the fisheries.

The simple fact we take to be this; that the success of the fisheries, like that of every other speculation, must depend mainly on the two great hinges on which all commercial enterprises turn, viz. supply and demand; where these exist to any great extent, and without any material fluctuation, the success of a fishery establishment cannot be doubtful. If, however, the supply be not equal to the demand, the article will be in danger of falling into the hands of monopolists, whose common practice is to add to the scarcity in order to enhance the price. By thus contracting the supply within its natural limits, they not only raise the price, but reduce the demand. On the contrary, where the supply exceeds the demand, the market becomes glutted, the prices are too low to afford a suitable return for the expenditure, and the adventurers withdraw their capital, and turn it into some more profitable channel. But a certain and steady demand creates competition, and regulates the supply according to the wants of the consumer, at a fair and reasonable price.

Want of steady demand.

It is the want, we conceive, of this steady and constant demand, and not of supply, which has at all times operated to the discouragement of the British fisheries. That the supply of fish is most abundant, and indeed inexhaustible, on the coasts of Great Britain, has never been called in question. "The coasts of Great Britain," says Sir John Boroughs, "doe yield such a continued sea-harvest of gain and benefit to all those that with diligence doe labour in the same, that no time or season in the yeare passeth away without some apparent meanes of profitable employment, especially to such as apply themselves to fishing; which from the beginning of the yeare unto the latter end, continueth upon some part or other upon our coastes, and these in such infinite shoales and multitudes of fishes are offered to the takers, as may justly move admiration, not only to strangers, but to those that daily bee employed amongst them." That this harvest, ripe for gathering at all seasons of the year, without the labour of tillage, without expense of seed or manure, without the payment of rent or taxes, is inexhaustible, the extraordinary fecundity of the most valuable species of fish would alone afford abundant proof. To enumerate the thousands and even millions of eggs which are impregnated in the herring, the cod, the ling, and indeed in almost the whole of the esculent fish, would give but an inadequate idea of the prodigious multitudes in which they flock to our shores; the shoals themselves must be seen, to convey to the mind any just notion of their aggregate mass. The herring, for instance, makes its appearance in shoals, the dimensions of which are measured by leagues and miles, moving steadily along in close array, and in columns of such depth from the surface downwards, as to have obtained the name amongst the northern nations of *herring mountains*. These columns advance yearly from the northern seas, early in the spring, with undiminished numbers, though preyed upon by a multitude of enemies, as well from the shore, as in their native element and in the air. Wherever their vast columns proceed, if unmolested by man, they have to sustain constantly the attacks of the grampus, the porpoise, the shark, cod-fish, and even haddocks; and if they approach the surface, they are seized by the innumerable flocks of sea-gulls, gannets, and other aquatic fowls, which hover along their line of march. Where the spawn of the herring is usually deposited, naturalists do not seem to be agreed; but as young herring have not been caught, either with the old ones, or within the limits of the fishery, and as the shoals invariably proceed from the northward, making their first appearance about the Zetland Islands in the month of April, it has generally been thought that their winter habitation is within the Arctic circle, under those vast fields of ice which cover the Northern Ocean, where they fatten on the swarms of shrimps and other marine insects which abound in those seas, and which afford also the principal food of the whale. Here it is supposed they deposit their spawn, and, on the return of the sun toward the northern hemisphere, again rush forth in those multitudinous hosts which exceed the power of the imagination to conceive.

The pilchard, which is a species of the same genus as the herring, is also a migratory fish, but makes its appearance from the southward, in vast shoals, inferior only to those of the herring; which is also the case with the mackerel, both being of equal or greater fecundity with the herring, and liable to the attacks of the same enemy. The salmon is equally irregular in its visits to the coasts of Great Britain and Ireland, and approaches the mouths of our rivers in shoals, which they ascend to considerable distances, surmounting every obstacle in order to find a safe and convenient spot where to deposit their innumerable eggs. The various kinds of white fish, as turbot, sole, plaice, whitings, and haddocks, are plentifully dispersed throughout various parts of the British seas, affording an inexhaustible supply of fresh fish for home consumption during the whole year, without the least apprehension of such supply being exhausted or diminished. On the eastern shores of Great Britain, and on the rocky coasts of the Orkney and Zetland Islands, are plenty of lobsters, which would more than supply the market of the metropolis with this article of luxury, as the south-eastern and southern coasts do the oyster with its nutritious food for eight months in the year.

Use sh scarce know the ir rior.

In spite, however, of this abundant supply of wholesome, palatable, and nutritious food, yielded by the surrounding seas of Great Britain, every acre of which is infinitely more productive than the same quantity of the richest land; notwithstanding that these salt water fields are perpetually "white to harvest," it is a remarkable fact, that in the inland and middle counties of England, the labouring classes scarcely know the taste of fish, which, of late years, has become a scarce article, even in most of the maritime counties. Formerly salmon, whilst in season, was the common food of all ranks in the northern counties bordering on the sea, and in most parts of Wales, and what could not be used fresh was salted for winter consumption; there was scarcely a family in the neighbourhood of a sea-port or salmon fishery that did not lay up a supply of pickled salmon for the winter. In the progress of luxury, well-boats were invented to convey the fish fresh to the London market, yet these were not sufficiently numerous to carry off the whole supply. The next contrivance was that of packing them up in ice, by which they could be kept fresh for a length of time, and conveyed either by land or water to the metropolis; since which the local markets have nearly been left without a supply, even for the few families who can afford to pay an extravagant price for the article. That price in London was for a long time greatly enhanced, by the trade being almost exclusively in the hands of monopolists, who had it at all times in their power to create an uncertainty in the supply, and consequently a fluctuation in the price, both of which are detrimental to an augmented demand; but that monopoly has been recently broken down.

That a narrow confined corner, at the very extremity of the metropolis, should have been allowed for such a length of time to exercise the privilege of absorbing all the fish brought within the radius of seven miles round its vortex, but ill accorded with the boasted good sense of these enlightened times. It needs scarcely be mentioned that Billingsgate was this favoured spot; holding by charter an injurious and hateful privilege, which, as Sir Thomas Bernard justly observes, "in the greatest and most populous city in the world, restricts the sale of an article of life to a small and inconvenient market, and has exclusively placed the monopoly of fish in the hands of a few interested salesmen." The establishment of that splendid and most commodious market, the Hungerford, has put an end to that injurious monopoly, and consequently reduced the prices and increased the quantity of this species of food for the use of the metropolis.

Obser tions o bounti

The encouragement given by the government in the shape of bounties appears to have contributed but little to the success of the fisheries. If a branch of trade once fairly established will not support itself without being bolstered up by bounties, it never can be worth carrying on. Bounties should only be continued for a definite time, and decreased gradually. Those on the fisheries should be given on the quantity procured, and the quality of those cured, and not on the instrument of their production; on the fish, and not on the vessel. It was proved by a committee of the House of Commons, in 1785, that the herring fishery absolutely cost little short of L.20,000 annually, which, on an average of ten years, was equal to L.75 per cent. on the value of all the fish that had been taken by the vessels on which it was paid. Adam Smith has justly observed, that a tonnage-bounty proportioned to the burden of the ship, and not to her diligence and success in the fishery, is not the best stimulus to exertion; it was an encouragement for fitting out ships to catch, not the fish, but the bounty; or to induce rash adventurers to engage in concerns which they did not understand, and cause them to lose, by their ignorance, more than was gained by the liberality of government. The carelessness of such persons, and the ignorance of those employed by them in curing and packing the fish, not only robbed the public purse, but destroyed the character of the article in the foreign market; where, if saleable at all, it fetched only an inferior price, whilst the skill and attention of the Dutch secured for their fish that preference to which they were justly entitled. The change of the bounty, however, from the tonnage to the quantity and the quality of the fish caught and cured, with the regulations adopted by the acts of 48th and 55th Geo. III. have had the good effect of raising the character, and consequently increasing the demand, for British fish in the foreign markets, where the herrings in particular are now held in equal estimation with those of the Dutch. The bounty, granted by the act 48 Geo. III. c. 110, is 2s. per barrel on all herrings branded by the proper officers, and 4s. a barrel granted by the act 55 Geo. III. c. 94, and is so considerable that at this time it amounts to a sum not less than L.30,000 a year.

Experi ments showin the pos bility o extendi the de mand.

It would appear, however, that all which is now wanting for the encouragement and extension of the British fisheries, is a constant, steady, and increased demand in the home and foreign markets. An experiment made by Mr Hale, one of the members of the committee for the relief of the manufacturing poor, proves decisively how easy it would be to introduce the general use of fish in the metropolis. He agreed with some fishermen to take from ten to twenty thousand mackerel a day, at a price not exceeding 10s. the hundred of six score, or at a penny a piece, a price at which the fishermen said they could afford to supply the London market to any extent, provided they were sure of a regular sale. On the 15th of June 1812, upwards of 17,000 mackerel were sent to Spitalfields, and sold at the original cost of a penny a piece, to which place women were employed to carry them from Billingsgate until eleven o'clock at night. They were purchased with great avidity, and vast numbers continued to pour into Billingsgate. They were sent to other parts of the town, and sold to the poor at the same rate; and it is stated that "the supply increased to so great a degree that 500,000 mackerel arrived and were sold in one day." The whole cost of this experiment, for the distribution of fresh and sweet mackerel at a penny a piece, was L.55. 10s. expended chiefly in the carriage from Billingsgate. In like manner, it is estimated that herrings might be supplied in any quantity at one halfpenny a piece, and cod, haddocks, whitings, flounders, &c. proportionally cheap, provided a steady demand was created, as it is presumed there would be, by the establishment of several regular markets in different parts of the metropolis.

Another experiment of the committee shows how easily a demand for salted or corned fish might be created in the inland counties. They contracted for 200 tons of corned cod, caught and cured on our own coast, and also for 400,000 corned herrings. The former was supplied to the distressed manufacturers of Sheffield at twopence halfpenny a pound, and the latter at the rate of two for three halfpence. Here, as well as in other parts of the country, the poor, it is stated, received the fish distributed among them at low prices with the liveliest gratitude; and one gentleman in Worcestershire states that "the herrings, in particular, have proved a bonus to the poor of the most essential benefit. We sold them," he says, "at a very low and reasonable rate, on account of the extreme indigence of the purchasers; and they have produced L.40 (profit), which, after the expense of carriage is paid, will be laid out in employing the poor in repairing the roads."

It deserves to be mentioned, as an instance of the certainty of a supply to answer the demand, that, when the Association was formed in 1812, the North Sea and Iceland fishery had for some time entirely ceased; but, on the committee offering the fishermen L.18 a ton for all the fish they should catch and cure, they supplied, in the first instance, 100 tons of dry-salted, and fifty tons of fresh cod; in the second, 200 tons of dry-salted, and 400 tons of fresh; in the third, 600 tons of dry-salted, and 300 tons of fresh; in all 1350 tons of fish were taken and brought to market in consequence of this offer, not a fish of which would otherwise have been caught.

The obvious policy, then, to be pursued for extending the British fisheries, is by creating an extended and constant demand. In the foreign markets this can only be done by the care and attention bestowed in curing the fish, so that, in point of quality, it may compete with those of the Dutch and other nations of the continent; a point which we have just now happily attained; but in the supply for home consumption every thing almost yet remains to be done. The Fish Association have, however, clearly shown the way of proceeding to obtain this desirable end; they have proved that, not only in the metropolis, but in the interior of the country, the poor have none of those prejudices which were ascribed to them, against the use of fish, when it is fresh and sweet, and when they are able to procure it at a moderate price. A free circulation, by means of markets established in the metropolis and at all the fishing ports, might effect this to a certain degree; but, in addition to these, some artificial expedients might be advisable, for a time at least, to raise and keep steady the demand. It is much to be regretted that Queen Elizabeth, who was well aware of the importance of the fisheries in a political as well as economical point of view, did not, in regulating the church ritual, ordain two days in every week to be set apart by Protestants as fish days, which would have created a steady and permanent demand for fresh and salted fish in every part of the United Kingdom. Such an ordinance might, in her reign, have been enforced, and long habit would have reconciled people to the observance of those days in our times; but it would be in vain to attempt the introduction of any such custom in the present refractory generation. There seems, however, to be no good grounds of objection to those who are maintained at the public expense being fed twice a week with a wholesome meal of fish. It is neither just nor politic that, whilst the poor labouring man, after toiling the whole week, can scarcely procure a little brown bread and a few potatoes for his wife and children, the indolent pauper should feed on the best white bread and choice butchers' meat. Supposing the number of paupers receiving parish relief, of convicts in the hulks, criminals in the jails, and, in short, all those who are fed at the public expense, to amount only to 1,000,000; and that to each was served out, twice a week, a sufficient allowance of good fresh fish, corned cod, or salted herrings, according to the season of the year and the situation of the parties, which could be amply provided for the value of three pence a head, the annual demand for fish, from this source alone, would amount to the sum of L.1,300,000. The voluntary consumption of the labouring poor would be at least equal, could an adequate supply be obtained at a cheap rate; and that it might will readily be inferred, when it is stated that, in the herring season, these fish may, on an average, be purchased at the stations for sixpence a hundred, whilst the salt required to cure them costs about one penny. Supposing the whole expense of a hundred to be one shilling, and one shilling more for land carriage to the farthest point in the interior, and allowing the retailer a profit of 100 per cent., a good salted herring might still be purchased for one halfpenny, and two herrings, with a few potatoes, would furnish a wholesome palatable meal. Salted or corned cod would be supplied at an almost equally cheap rate; and thus the quantity of food for the subsistence of man would be greatly increased, the fisheries encouraged, the consumption of butchers' meat lessened, and more pasturage converted into corn-lands, by which the enormous sums of money which are annually sent out of the country for the purchase of foreign corn would be employed at home. At present we have to trust for a supply of this "staff of life" to a miraculous plenty or a ruinous importation.

Political importance of the fisheries.

It would be superfluous to dwell on the political, economical, and commercial importance of encouraging and improving the fisheries, to an insular empire like ours. We shall only observe, that, by their augmenting the quantity of food, there would necessarily result a reduction in the prices of all the necessaries of life; the condition of the labouring poor, the artificers, and trades-people, would as necessarily be improved; they would not only be the means of rearing and supporting a bold and hardy race of men for the defence of the sea-coast, but also of creating a nursery of excellent seamen for the navy in time of war, and of giving them employment when peace may render their further services unnecessary. If the fisheries flourished to that extent to which they appear to be capable, every seaport, town, and little village on the coasts, or on the banks of the creeks and inlets, would become a nursery of seamen. It was thus in Holland, where the national and natural advantages were very inferior to those of Great Britain; for it is well observed, in the *Report of the Downs Society*, that Holland produces neither timber, nor iron, nor salt, all of which are essential to fisheries, and all the natural produce of Great Britain; that Holland has no herrings upon her own coast, whilst the coasts of our island abound with them and other fish, at different if not at all seasons of the year, so that there are few if any months in which shoals of this fish in particular are not found on some part of our shores; and lastly, that her population is under 3,000,000, whilst ours amounts to about 18,000,000, giving to our fishermen six times the consumption of a home market that the Dutch can command.

Though the occupation of a fisherman is dangerous, laborious, and precarious, yet it does not appear that the want of sufficient hands has at any time retarded the progress of the fisheries. At this moment about 20,000 seamen, receiving pensions of from L.7 to L.20 and upwards, according to their wounds, infirmities, and length of service, are located for the most part along the sea-coasts of the united empire, all of whom, not otherwise employed in the coal and coasting trade, would readily add to the little pittance they receive from a grateful public, by being employed on an element so congenial to their habits.

The report of the committee which sat in the year 1833 to inquire into the present state of the Channel fisheries, ascribes the decline of these fisheries to other causes than the want of demand. They report that they find the British Channel fisheries to be generally in a very depressed and declining state; that they appear to have been gradually sinking since the peace in 1815, and more rapidly during the last eight or ten years; that the capital employed does not yield a profitable return; and that the number of vessels and boats, as well as of men and boys employed, is much diminished: and they ascribe the principal causes that have tended to produce this depression, *first*, to the extensive interference and aggressions of the French fishermen on the coasts of Kent and Sussex; *secondly*, to the large quantity of foreign-caught fish illegally imported and sold in the London market; and, *thirdly*, to the great decrease and comparative scarcity of fish in the Channel.

1. With regard to the interference of the French fishermen, they have undoubtedly, as we have observed, an advantage over ours, by fishing within half a league of the shores of Kent and Sussex, and frequently much nearer; but if it be true, as is stated, that they have now between 200 and 300 sail out of Boulogne alone, being more numerous and larger than those of our countrymen, manned with double or treble the number of men, and carrying nets and fishing-gear of a much larger and heavier description, what can possibly occasion this great difference in favour of the French over us, but the very great demand for fish in the one country and the want of it in the other. It is the great demand alone that affords them capital to send out more boats, and of a larger size, with more men in them, than our fishermen, for want of demand, can afford to do. In fact, fish in a fresh, or salted or dried state, may be said to be in universal demand throughout France, whilst in England the supply is almost wholly limited to the capital, and a few large towns at no great distance from the sea-coast. The middling and lower orders in England, generally speaking, have no great relish for fish; they give the preference ten times over to bacon, and every species of butchers' meat. The herring and mackerel fisheries are stated to have been nearly abandoned, whilst the French continue on our coasts during the whole of the season of these fisheries, making a constant practice of selling their cargoes of fish at sea, and shipping them into carrier boats from the Thames and other ports, and into boats which board them in the bay of Dover, for the supply of the London market. This practice requires but small capital and little outlay. Such an intercourse may also have for its object the more profitable occupation of smuggling, as well as trafficking for fish. A further grievance, and one that certainly ought to be prevented, is, that at other seasons of the year the French come every morning from Boulogne and other places, into the English bays, and there drag with nets for bait in the shallow waters, close upon the shore, taking and destroying, in immense quantities, the young and unsizeable fish; and this is done at those periods of the year when they are not permitted to fish in the bays upon their own coasts; a practice which tends materially to diminish the quantity of grown fish on our coasts.

The suggestion of the committee, that, in order to remedy the grievances at present sustained by the English fishermen, foreigners should be prevented, at all seasons of the year, from fishing within one league, or such other distance, of the English coast, as by the law or usage of nations is considered to belong exclusively to this country—this would undoubtedly be most desirable if it could be effected; but we have conceded this point, and ancient *usage* is unfortunately against us, and the *law* cannot remedy it; the grievance can only be removed by mutual agreement. Measures, however, it is presumed, might be taken for the better preservation of the spawn and brood of fish in the bays and shallow waters upon our coast, which is of the utmost importance.

2. The importation of foreign-caught fish is prohibited by various acts of parliament, under heavy penalties and forfeiture, imposed on the parties, both foreigners and British subjects, who may be implicated in such a transaction. The kinds of fish exempted from prohibition are, turbots and lobsters, eels, stock-fish, anchovies, sturgeon, botargo, and cavear; these may all be, and are, legally imported,—turbots and eels generally by the Dutch, and almost all the lobsters from the coast of Norway. The committee however report, that, notwithstanding the prohibition and penalties, it appears in evidence that about one third of the fish supplied to the London market is procured from foreigners, including, however, in that estimate, the turbots, eels, and lobsters. It is further stated that the violation of the acts of parliament has of late years been practised openly, and without interruption on the part of the government or officers of his majesty's customs, arising probably, as the committee think, from some misapprehension of the provisions of the statutes. The practice, it appears, prevails chiefly off the mouth of the Thames, and upon the coasts of Kent and Sussex, and it operates most injuriously during the mackerel and herring seasons.

Our fishermen complain that they are much injured by the continued permission given to foreigners to import turbots free of duty; and it is stated in evidence, that if relief were afforded in this respect to the English fishermen, the markets of this country would still be adequately supplied with this valued species of fish, without increased prices; and that the alteration of the law, in this respect, would tend very materially to revive the fisheries connected with the coasts of Norfolk and Essex, and also with those of Kent and Sussex, and be of great value to our fisheries in general. There do not seem to be any political grounds for opposing such an enactment, as the English fishermen are not allowed to import any description of fish into France or Holland. Why should not our fishermen, when driven by stress of weather or for repairs into a French or Dutch port, be permitted to sell a sufficient portion of their fish to provide themselves with necessaries for their support, whilst this indulgence is granted to those of France and Holland in the ports of England?

3. The scarcity of fish in the Channel, with the exception of mackerel and herring, which are fish of passage, is said to have increased during the last fifteen or twenty years, occasioned by the great destruction of the spawn and brood of fish consequent on the non-observance of the laws which at present exist for their preservation. By the statute 3 James I. "for the better preservation of sea-fish," it is enacted, that "every person who shall fish in any haven, harbour, or creek, or within five miles of the mouth of any haven, harbour, or creek, with any draw-net or drag-net under three inches mesh, or with any net with canvass or other engine or device, by which the spawn, fry, or brood of sea-fish may be destroyed, shall forfeit such net, and also ten shillings." By 14 Charles II. "for regulating the pilchard fishery," from the 1st June to 30th November no person shall take fish in the high sea, or in any bay, port, creek, or coast of Cornwall or Devon, with any drift-net, trammel, or stream-net, or other nets of that sort, unless at the distance of one league and a half from the shore," under penalty of forfeiting the nets or value, and one month's imprisonment of the offender. The 1st Geo. I. enacts "that the meshes of nets used at sea upon the coast of England shall not be less than three inches and a half from knot to knot," under penalty of forfeiture of nets, and of L.20, with power of imprisoning the offender. The 33d Geo. II. provides "that no person shall kill or destroy, or knowingly have in his or her possession, either on the water or on shore, or shall bring to shore, or offer for sale or exchange, any spawn, fry, or brood of fish, or any unsizeable fish, or fish out of season," under the penalty of twenty shillings, and forfeiture of the baskets or other packages containing them.

These salutary statutes seem to have been neglected, and, in the opinion of the committee, ought to be revised, and the provisions extended; and that conservators or overseers should be appointed for the purpose of enforcing the act. The French take care to protect their bays and breeding-grounds from the 15th April to the 1st September, the intermediate months being the spawning or breeding season of the fish, when the young brood have not become of a sufficient size or strength to take refuge in deeper waters. It is stated in evidence, that in the year 1816 the Trowl fishermen on the coast of Devon, acting under the advice of the present Lord Vernon, tried the experiment by mutual consent, of preserving their breeding-grounds undisturbed from the 1st of July to the 20th of September in that year, the consequence of which was a greater abundance of fish in the ensuing season than had ever before been known upon that coast; and the fishermen were desirous that the restraint which they had thus voluntarily imposed upon their fishing should in future be enforced by law. Accordingly, in 1819 a bill was brought into the house, "to prevent the destruction of the brood and spawn of fish," which, however, was thrown out on the third reading; but in the year 1822 the same bill was again brought in and passed the Commons, but was lost in the Lords; since which no further attention appears to have been paid to the subject, and thus the evils complained of have continued unredressed, and, as it appears, are increasing.

The stow-boat fishery, or catching of sprats for manure, which prevails principally upon the Kentish, Norfolk, and Essex coasts, is highly injurious to the spawn and brood of fish, the nets used being so very fine as to enclose not only sprats, but the spawn and young breed of all other kinds of fish. The demand for this species of manure is said to be so extensive, that there are at this time from 400 to 500 boats engaged in stow-boating on the Kentish coast only, each remaining out till it has obtained a full cargo of dead fish for the purpose of manuring the land. The legislature ought certainly to put a stop to this most injurious practice, or at least confine it within specific limits both as to time and space.

It is stated that the herring and pilchard fisheries have declined considerably, not so much from the competition of French fishermen, as from the heavy duty levied at Naples of sixteen shillings a barrel, which amounts nearly to a prohibition; the pilchard fishery also suffers from the same cause. It appears also that the clergyman demands tithe to the amount of between two and three pounds per annum for each herring or mackerel boat, which appears not to be more than about one-eightieth part, after deducting the boat's expenses.

It is suggested that it would afford some small encouragement to the fisheries, by increasing the inland consumption, if the fish-carts were allowed to pass the turnpike gates free of tolls. This exemption, if granted, would particularly relieve the fisheries at Yarmouth, Harwich, Dover, Folkestone, and Hastings, and increase their supply of fresh fish, particularly of mackerel, to the London market. London, however, is the best supplied market for fish, perhaps, in the kingdom, and it does not appear that any monopoly or injurious regulations now exist, either in the mode of supplying the market or in the sale of fish.

It may be curious to see the weekly supply of different kinds of fresh fish for the London market, that is to say, for six days from the 19th to the 24th of June inclusive:—

Salmon........................	253½	boxes.
Turbot........................	3,153	individuals.
Lobsters........................	131,000	do.
Mackerel........................	131,700	do.
Whitings........................	31,175	do.
Soles........................	164	bushels.
Maids and plaice............	1,045	do.

Besides fresh cod-fish, skate, haddock, and other fish in smaller quantities.

Actual progress of the British herring fishery.

With all the impediments to an extended use of fish in the home market, and notwithstanding the established character which the Dutch fish have always borne among foreign nations, it is consoling to find that the herring fishery generally has been in a progressive state of improvement. Since the act of 48 Geo. III. appointing commissioners, separate and distinct from the customs and excise, to superintend the distribution of bounties, stationing of officers versed in the trade of the herring fishery, persons who had experimentally and practically followed that fishery as a trade, but who are excluded from all interest or participation in the trade, the herring fishery has become with us, as it was with the Dutch, an object of national concern; the good effects of which are most sensibly felt in every part of the coast where it has regularly been established, by the labour it provides, the demand it creates for a variety of articles required by it, and the money it throws into circulation. By this act, an annual report by the commissioners, of their proceedings, ending the 5th April, is required to be presented to parliament each session; containing the details of the fishery of the preceding year, together with such observations and suggestions as may have occurred, or been communicated, to the commissioners, in the interval between the reports. In the report of the year ending 1814, they had stated, "that the superior value of herrings branded by the officers of the fishery, in point of quality, weight, and measure, was becoming every year more generally acknowledged, even in markets where till of late gutted herrings were not much prized; and this they ascribe to their refusal of every application for allowing bounty on barrels out of the full size of thirty-two gallons, and to their having directed prosecutions against the proprietors of such herrings as had been seized, for being presented for bounty in undersized barrels; and that, with other precautions respecting the proper cure of the herrings, the desired effect had been produced, of raising the character of British herrings in the foreign market." In their report of 1816, they state that they have had their attention turned to different matters calculated to improve the cure of herrings, and to raise the character of the British fishery in foreign parts; that a communication, made to them by a mercantile house of respectability, on the subject of increasing the exportation of herrings to the Continent of Europe, had been printed, and distributed among the curers throughout the kingdom; that regulations had been adopted for improving the construction of barrels intended for bounty; that the boats of the fishermen had been properly fitted up for the reception of herrings; that bounty had been refused on all barrels not full of pickle; and that the strictest orders had been given to the officers of the fishery, to apply the official brand in no case, unless both herrings and casks were in every respect such as would do credit to the establishment. In the year 1817, the commissioners point out in their report the great increase which had taken place in the exportation of British herrings to the Continent of Europe, in consequence of the communication made to and the regulations adopted by them, as contained in the preceding report; and, in the year 1818, they observe that they had received a memorial on the subject from Hamburg, signed by a number of herring merchants of that port, bearing testimony to the improvement which had taken place in the quality of British herrings, and pointing out the means of raising their character still higher. This memorial the commissioners likewise caused to be printed and distributed amongst the curers, which they accompanied with such additional observations as they conceived to be necessary, and which they state to have produced the most salutary effects. They conclude their statement with the gratifying intelligence, that the character of the British fishery is rising both at home and abroad; for that, whilst the quantity of herrings cured *gutted* is annually increasing, the quantity cured *ungutted* is every year diminishing; that, great as the amount of the fishery had been in the course of that year, the demand had fully kept pace with it; and that, at the end of the season, few herrings remained unsold in the hands of the curers. They further report, that whilst the exportation to the Continent of Europe had nearly equalled that of the preceding year, and the exportation to the West Indies and Ireland had increased, a new market had opened in the East Indies, to which different shipments of herrings had been made, by way of experiment, both from Greenock and London; that, from the former of these places, upwards of 1300 firkins were exported to Calcutta, all of which, they understood, were purchased by Europeans there at 20s. to 25s. per firkin; and that it was the intention of the exporter, in consequence of this encouragement, to ship a larger quantity next season; so that the commissioners trust that India will soon become a permanent and valuable market for the consumption of British herrings. The report thus concludes: "It is impossible to state, within the compass of this report, the advantages resulting to the community from the prosperity of the herring fishery; but the commissioners think it their duty briefly to mention that the effects thereof are felt in almost every part of the kingdom. The fishermen have, in many cases, been enabled, by the produce of their industry, to replace the small boats formerly used, by new boats of much larger dimensions, and to provide themselves with fishing materials of superior value. The number of boats and of fishermen has been greatly increased; while, by the general introduction of the practice of *gutting*, a valuable source of employment has been opened to thousands of poor people, who now annually resort to the coast during the continuance of the fishing season, and there earn a decent livelihood in the operations of gutting and packing. New dwelling-houses and buildings, on a superior construction, for the curing and storing of the herrings, are erecting at almost every station along the coast; while the demand for home wood for the manufacture of barrels affords a source of profit and employment to numbers of people in the most inland parts of the country."

The following report for the year ending 5th April 1819, exhibits at one view the then state of the herring fishery at the different stations in Great Britain, under the superintendence and control of the commissioners, and the officers appointed by them.

Progr of the H- land fi ery.

This rapid progress shows that there is no art or mystery in the catching and curing of herrings that the English cannot attain as well as the Dutch; and the same thing is further proved by the successful experiment made by the Downs Society of Fishermen, in the report of whose proceedings it is stated that herrings had been taken within the Cinque Ports of a quality so nearly resembling the deep-sea fish, that they were cured and sold as the best Dutch herrings. It will also be seen by Table I. that the progressive increase of the herring fishery is confined to Scotland; and that the quantity brought under the inspection of the officers in England amounts not to one twenty-second part of the whole; whilst the flourishing little town of Wick alone furnishes nearly one fifth. But the most extraordinary increase is that which has taken place in the neighbouring county of Sutherland. Formerly the people of this county were contented to hire themselves as fishermen to the adventurers of Wick. In 1814 they attempted a fishery on their own account, and the mouth of the Helmsdale river was fixed upon as the station. A storehouse and curing-house were here erected; and the boats were manned by the people brought from the mountains and the interior of the country. Every thing was new to them in the employ they were about to engage in. The fishing commenced on the 20th July, and ended on the 3d September 1814; and the produce of four boats was respectively L.105. 3s., L.83. 8s., L.96. 8s., and L.148. 3s. They were manned by four men each, so that they made, on an average, rather more than L.27 a man. In 1815 the number of boats employed amounted to fifty, almost entirely manned by Sutherland men; and the number of barrels caught and repacked exceeded 4000, chiefly gutted. In 1817 this fishery gave employment to about 200 tenants, seventeen coopers, and 130 women; in 1818 to seventy coopers, 520 women, 700 men, 140 boats; and, in the year 1819, the quantity caught and cured at Helmsdale, as appears by the table, amounted to no less than 22,876 barrels, besides upwards of 100,000 cod and ling. Whilst the herring fishery was making these rapid strides in the Highlands of Scotland, the ancient town of North

Yarmouth, which owes its existence to the herring fishery, and in the time of Edward III. had an act, usually called "the statute of herrings," passed in its favour, for the regulation of its herring-fair, exhibited only the small number of 1039 barrels.

White fishery.

And not only does North Britain take the lead in the herring-fishery, but it has also availed itself of its favourable situation for carrying on that branch which may be reckoned next perhaps in importance, namely, the cod and ling fishery. The whole extent of sea, from the neighbourhood of the Orkney and Zetland Islands, to Iceland on the one hand, and to the coast of Norway on the other, and along the eastern and western shores of Scotland, to the Flemish banks on the east and the coast of Ireland on the west, may be considered as one great fishing domain, over which the different species of the cod genus are most plentifully dispersed; as are also turbot, skate, soles, haddocks, and whitings. These fish, which constitute collectively what is usually called the *white fishery*, surround as it were the whole of North Britain, and give to that portion of the united kingdom advantages which its southern neighbours cannot boast of.

Turbot fishery.

The only fishery perhaps which neither the Scotch nor the English follow up with the same success as the Dutch, is that of the turbot, the finest of which are supposed to be taken upon the Flemish banks. The turbot fishery begins about the end of March, when the Dutch fishermen assemble a few leagues to the south of Scheveling. As the warm weather approaches, the fish gradually advance to the northward, and, during the months of April and May, they are found in great shoals on the banks called the Broad Forties. Early in June they have proceeded to the banks which surround the small island of Heligoland, off the mouth of the Elbe, where the fishery continues till the middle of August, when it terminates for the year. The mode of taking turbot is as follows: At the beginning of the season the drag-net is used, which, being drawn along the banks, brings up various kinds of flat fish, as soles, plaice, thornbacks, and turbots; but when the warm weather has driven the fish into deeper water, and upon banks of a rougher surface, where the drag-net is no longer practicable, the fishermen have then recourse to the hook and line. Each line extends from one to nearly three miles in length, and is armed with six, seven, or eight hundred hooks, fixed to it at the distance of several yards from each other. To keep these long lines properly stretched, and prevent their being carried away by the tide, heavy masses of lead in some places, and small anchors in others, are attached to them. The hooks are baited with the common smelt, and a small fish resembling an eel, called the gorebill. Though very considerable quantities of this fish are now taken on various parts of our own coasts, from the Orkneys to the Land's End, yet a preference is given in the London market to those caught by the Dutch, who are supposed to have drawn not less than L.80,000 a year for the supply of this market alone; and the Danes from L.12,000 to L.15,000 a year for sauce to this luxury of the table, extracted from about one million of lobsters, taken on the rocky shores of Norway, though our own shores are in many parts plentifully supplied with this marine insect, equal in goodness to those of Norway.

Salmon fishery.

Scotland has very decidedly the advantage over England in the salmon fishery, which, if not of superior value, may be allowed to rank next in importance to the cod fishery. This fish being rarely caught except in estuaries or rivers, may be considered as in a great degree private property; and it may therefore be presumed that the fishery is conducted to the greatest possible extent and advantage. From the extremity of the Highlands, and from the Orkney and Zetland Islands, these fish are sent to the London market, as before mentioned, in ice; and when the season is at its height, and they catch more than can be taken off hand fresh, they are then salted, pickled, or dried, for winter consumption at home, and for the foreign markets. Perhaps the fishery of the Tweed is the first in point of the quantity caught, which is sometimes quite astonishing, several hundreds being taken at a single draught of the net. It is here where the kitted salmon is principally prepared for the London market, being first boiled and then pickled with vinegar.

The decrease of salmon in the English and Scotch rivers, particularly of late years, is a fact as to which there can be no manner of doubt. Much unsatisfactory discussion has taken place as to its causes, which are probably of a very diversified character. A good deal has been ascribed to the increase of water machinery on the banks of the different rivers; but we hardly think that this could have much influence, except perhaps in the case of the smaller class of rivers. *Weirs* or salmon traps have also been much objected to; though, as we have been assured, with still less reason. On the whole, we are inclined to think that the falling off in the supply of this valuable fish is principally to be ascribed to the temptation to over-fish the rivers, caused by the extraordinary rise in the price of salmon; to the prevalence of poaching; and, more than all, to the too limited duration of the *close time*. In 1828, after a great deal of discussion and inquiry, an act was passed (9 Geo. IV. c. 39), which has done a good deal to remedy these defects, in as far at least as respects the Scotch fisheries. The rivers are to be shut from the 14th of September to the 1st of February; and every person catching or attempting to catch fish during that period is to forfeit not less than L.1 and not more than L.10 for every offence, besides the fish, if he have caught any, and such boats, nets, or other implements as he may have made use of. Pecuniary penalties are also inflicted upon poachers and trespassers; and provision is made for the watching of the rivers. We understand that this act has upon the whole had a very good effect; though it is believed that it would be better were the *close time* extended from the 1st of September to the middle of February.

The late Sir Humphry Davy delivered into the hands of the committee a paper on the natural history of the salmon, which he concludes with the following observations. "There is a general complaint," he says, "of the diminution of salmon in fisheries. In the Thames it can scarcely be said to exist; and even in the Avon, the Severn, and the Trent, it is becoming comparatively a scarce fish. The great northern fisheries, and the Irish fisheries, are much less productive than formerly." The simple remedies for this national evil he states to be, 1. to suffer more fish to spawn, and fish of all ages and sizes; 2. to prevent any fish from being killed in rivers after spawning; and, 3. to prevent the young salmon or salmon fry from being killed.

He is of opinion that each variety of salmon or salmon trout affects a particular river, and always returns to it; that therefore all stake fishings should be abolished, as they enable persons having no interest in the river to cut off almost entirely the supply of fish, for salmon do not go far out into the sea, and always return along the coast, scenting out, as it were, their own river; and that a strong net put across an estuary might destroy in one year the whole fishery of a river. He recommends that no close wears should be allowed, but that there should be always a free passage for fish, so that early fish may go up as well as late fish; that no machinery should be allowed in a river, by which spawning fish may be killed; that nets should be limited to a certain size, so as to render it impossible to sweep a river; and that no angling should be allowed in salmon rivers till May, nor after October.

The annual value of the Scotch and English fisheries, and the number of persons and craft employed on them, are but vaguely stated in the statistical reports of the several maritime counties of Great Britain; and in some of them the subject, important as it certainly must be considered in our economical system, and as connected intimately with the subsistence and employment of the labouring poor, is altogether omitted. This defect is more particularly to be regretted at this moment, when inquiries are anxiously making, not only how to employ a superabundant population, but to ascertain to what extent the powers of the country are capable of supplying the means for its subsistence. Indeed we conceive that a statistical survey of the British fisheries, as far as it could be made out, would afford a most valuable document in aid of a more complete investigation of that branch of political economy which relates to the employment and the feeding of the people. The following brief account must, therefore, be considered as very imperfect. It is to be understood that the returns of the herring fishery, as given in the preceding table, are not taken into the account.

Sutherland. The waters in which the salmon fishery is chiefly carried on in this county are those of Naver, Helmsdale, and Brora, and the rent of these fisheries is about L.1700 a year; the produce L.6800. In one year, from December to March inclusive, were caught between Bighouse Bay, on the north coast, and Rou-stoir in Assynt, on the west coast, 30,000 lobsters, which at three pence a piece, the price paid to the fishermen, amounted to L.375. They were carried in smacks to the London market, where at that season of the year their value was estimated at about L.7000. It is estimated that each of the thirty-seven boats on the coast of Assynt might produce L.100 a year. Three boats at Golspie are stated to make about L.150 a year by haddocks alone, which are consumed by the country people. Of the quantity of cod and ling exported no account is given, but these valuable fish are taken in great abundance on every part of the coast. Whatever opinions may exist with respect to the policy of the measures which have recently been adopted regarding the tenantry of this county, there can be but one in considering the late Duke of Sutherland as a great promoter of the fisheries, and a benefactor to all who are concerned in them.

Caithness. It is asserted, with every probability of truth, that there is no district in Europe better calculated for carrying on the fisheries, either in point of profit, variety, or extent, than Caithness. In the fresh waters of the county, and the seas by which it is surrounded, there are enumerated forty-five different kinds of esculent fish. Next to the herring, the cod fishery, near Thurso, may be reckoned as the most important. Indeed the whole coast of Wick and Latheron, and every part of the Pentland Frith, abounds with this valuable species of fish, as well as all the other kinds usually distinguished by the name of white fish. The herring fishery, as will be seen in the preceding table, holds a high place among the established fishing stations; and, in fact, the whole county feels the beneficial effects of an active prosecution of the fisheries, out of which has of late years risen a new town, near Wick, named Pulteney Town; and all the villages on the coast are in a progressive state of enlargement and improvement from the same source.

Ross and Cromarty. In the report of the agriculture of these counties, by Sir George Mackenzie, there are some excellent observations respecting the herring fishery, the decline of which, previous to the late act, he ascribes to the circumstance of salt being delivered to the fishers free of duty; which made the fishermen rely on the greater part of their expenses, and some part of their profits, being paid by the fraudulent practice of smuggling the salt for sale; and to such an extent was this practice carried, that it is broadly asserted "there is not a farmer in the Highlands who uses any other than fishery salt for butter, cheese, and other provisions; there is no other salt used in private families."

The cod fishery of Gairloch is the most productive of any upon the coast of Scotland. The fishing is from January to April. The fish are small in size, but rich, averaging about five pounds each when cleaned for salting. They are mostly pickled, and also dried, and sent to Ireland, Liverpool, and London. The average annual produce is about 20,000 cod, taken by twenty boats, each having about 400 hooks; which number, it is stated, might easily be doubled. For the success of this fishery, those who followed it were greatly indebted to the bounty and judicious assistance of Sir Hector Mackenzie.

Nairn and Moray. The principal fishery of this part of North Britain is that of salmon, chiefly in the rivers Nairn, Findhorn, and Spey, the whole of which, supposed to amount yearly to about L.25,000, is exported to the London market in smacks of eighty or a hundred tons burden, packed to the number of three or five in a box with pounded ice. These smacks keep the sea in all kinds of weather, and generally reach their destination from the fifth to the ninth day. When salmon begins to be too plentiful in the market, it is then boiled and sent up in kits. The price is so high where caught, that salmon is considered as a luxury, and is exhibited only at a feast.

Aberdeen. The salmon fishery is the most considerable in this county, and most productive on the Dee and the Don. The usual practice, formerly, was to salt the fish, pack them in barrels of about four hundredweight each, and export them to the south of Europe. In 1798 the quantity caught on the Dee was equal to 1890 of these barrels, and on the Don 1667 barrels. At present they are sent up fresh to the London market; and it is stated that the price, since 1768, has increased in a five-fold proportion, and that not more than one pound of salmon is consumed in the county for forty that are exported. The fishings on the Ugie, the Ythan, and the coast near these rivers, vary from 200 to 600 barrels. The ordinary sea fishing for haddocks, cod, ling, skate, turbot, halibut, &c. is stated to employ a number of fishermen, who carry on their occupation chiefly in small creeks, and that it brings in yearly from L.15,000 to L.30,000, the greater part of which is consumed within the county; excepting about 500 barrels of cod, and a considerable quantity of ling, exported from Peterhead; from which place also, and Aberdeen, the Greenland whale fishery has been carried on with great success. The whole of the fisheries connected with the county yield from L.80,000 to L.100,000 annually.

Kincardine. The sea fishing, or white fishery as it is usually called, is stated to have greatly fallen off in this county. In upwards of thirty miles of sea-coast, the annual value of the white fish caught, and chiefly consumed in the county, does not exceed L.6000, giving employment to about 303 fishermen, or 200 families, consisting of 900 souls. The number of boats is about forty-three, and of yawls twenty-seven. The salmon fishery is of more importance; that in the North Esk is farmed at upwards of L.2400 a year. This, however, is the principal fishery, all the other waters in the county not producing a rental of more than L.300 a year.

The Lothians. Excepting a limited herring fishery at Dunbar, and a local fishery for the scanty supply of the neighbouring towns, the only other fishery deserving of notice, as a branch of trade, in East Lothian, is the oyster fishery at Prestonpans. From this place there have been sent to fatten, in bays near the mouths of the Thames and Medway, thirty cargoes in one season, each cargo consisting of 320 barrels, and each barrel containing 1200 saleable oysters, which brought about L.2500; but the quantity consumed near the spot, and in Edinburgh, brought somewhat more, and this branch of trade gave occasional employment to about forty boats. In that part of the Frith of Forth which washes the coast of West Lothian, besides a herring fishery on a limited scale, a scanty supply of cod, haddocks, whitings, skate, flounders, crabs, lobsters, and oysters, is taken for the use of the neighbouring towns.

Dumfries. The only fishery of any importance in this county is the salmon fishery in the Solway Frith, and the rivers, chiefly the Annan, falling into it, the rents of which do not exceed L.1400 a year, and are supposed to be too high; the fishing having greatly decreased in consequence of the destructive engines made use of by the renters. It is stated by one gentleman, that the number of salmon taken is not equal to one in a hundred of those caught some forty years ago.

Inverness. The salmon fisheries in the lochs and rivers of this county are those of most importance, and let for about L.3000 a year. Those on Loch Beauly and Loch Ness are the most valuable. A singular method of taking salmon is described near Invermoriston, where the river flows in a narrow chasm between two projecting rocks: "The fisherman seats himself on a cleft of this rock, right over the cascade, with a spear in his hand, which has a line fixed to the upper end of the shaft, similar to the practice of fishing for whales with harpoons. Whenever the salmon makes a spring to gain the ascent over the cataract, the spearman strikes the fish and lets the shaft go, holding only by the line until the fish has exhausted his strength; then the spear and fish are thrown ashore by the stream, and taken out at the lower side of the pool."

Argyle. The whole of this county is so intersected with sounds, straits, lochs, and rivers, that the fisheries might be carried on within them to almost any extent; and fishing is accordingly the occupation of a great number of its inhabitants, there being in the whole about 1500 fishing-boats employed, of which Lochfine alone employs 600. The value of the fish caught is stated to be from L.40,000 to L.50,000 annually.

The Hebrides. The following is the whole account of the fisheries of these numerous islands, contained in the *Agricultural Survey:* "These fisheries," says Mr Macdonald, "do not belong to an agricultural survey; but they are of very essential importance to the Hebrides, and therefore merit notice in this place. They bring into those isles L.200,000 a year, at an expense perhaps of L.120,000, that is, they yield a clear profit in money and sustenance of L.80,000 to the natives. They occupy, together with the kelp manufacture, 2562 boats and vessels of every description, and for some months in the year 10,500 sailors. The fencible men, or those between the age of sixteen and twenty, being one fourth of the population, are 22,762; so that nearly one half of the effective male population is connected with the fishery. The principal fishing ports are Rothesay in Bute, Stornoway in Lewis, Tobermory in Mull, and Portnahaven in Islay; but the districts of Harris, Barray, South Uist, Skye, and various other islands, fit out a number of boats annually, or supply the Clyde busses with excellent mariners and fishermen."

English fisheries.

Berwick. London, it has been already observed, receives a very considerable portion of its fresh salmon from the fishery on the Tweed, that on the English side of the river alone giving employment to seventy small boats and about 300 fishermen. The value is not mentioned, but it is stated, in the *Survey of Durham*, that the rents amount to L.15,766 annually, and that, so far back as 1807, the number of boxes sent to London was 8445, of eight stone each, or 67,560 stone, which, at 16s. a stone, is L.54,000; besides what is killed for exportation, and what is sold fresh in the neighbourhood. The salmon, as they are caught, are packed in ice and sent away in the vessels well known under the name of Berwick smacks. Formerly it was all pickled and kitted, after being boiled, and sent to London under the name of Newcastle salmon; but the present mode has so raised the value of the fish, as nearly to banish this article of food from use among the inhabitants in the environs of the fishery, excepting as an expensive luxury. Within memory, salted salmon formed a material article of economy in all the farm-houses of the vale of Tweed, insomuch that in-door servants often bargained that they should not be obliged to take more than two weekly meals of salmon. It could then be bought fresh at 2s. the stone, of nineteen pounds weight; it is now never below 12s., often 36s., and sometimes two guineas, the stone.

The coast fishery is not of very material importance. It gives employment to upwards of 100 fishermen, at eight small fishing stations, with about twenty boats. The fish-carriers, under the name of *cadgers*, purchase and distribute the white fish, codlings, haddock, whitings, skate, halibut, and flounders, with a very few turbot, into the inland country, and often as far as Edinburgh. Cod and ling are generally contracted for, by the season, at a fixed price, by the fish-curers, who either salt and dry them, or barrel them, as the weather may serve. The fisheries on the coasts of Cumberland, Northumberland, Yorkshire, and Lancashire, are not once adverted to in the agricultural surveys of these counties.

Durham. The salmon fisheries in the Tyne, the Wear, and the Tees, are stated to have declined very much of late years, in consequence, it is supposed, of dams being thrown across these rivers, which prevent the fish from getting up to spawn.

Lincolnshire. On the coast of this county the fisheries appear to be almost wholly neglected. There is a little fish, however, in the east and west fens, called a stickleback, so numerous, that a man may make 4s. a day by selling them at a halfpenny a bushel. They also come from the sea into Boston Haven, where they are purchased for manure, being more powerful than any other kind known, even that of the whale refuse. It is almost unnecessary to state that, in this fenny county, pike, carp, perch, and tench, are most abundant.

Norfolk. The Norfolk surveys take little notice of the fisheries. It appears that the sticklebacks are caught in immense quantities in the Lynn river, about once in seven years, and are purchased for manure at the rate of sixpence or eightpence a bushel. It is mentioned, however, in Kent's *Norfolk*, that herrings to the amount of L.50,000 are annually exported, but that fish for the use of the inhabitants are neither regularly supplied nor cheap; that the best fish are lobsters, soles, and cod; that the whitings are small, and the oysters very large.

Suffolk. Besides the herring fishery carried on from Lowestoffe, by forty or fifty boats of forty tons each, the mackerel fishery is pursued during the season with great vigour. The value of this fish, caught in the course of six weeks, is stated to exceed L.10,000, independently of the usual kinds of white fish for the supply of the neighbourhood and the London market, the total value of the fishings being not less than L.30,000 a year. Most of the herrings caught here are dried and sent to the ports of the Mediterranean.

Essex. The oyster fishery is of all others the most important to this county. The principal station of the dredging-boats is at Mersea in Blackwater, which, with the Crouch and the Coln, are the most extensive breeding rivers in Essex. The oysters are brought from the coasts of Hampshire, Dorset, and other maritime counties, even as far as Scotland, and laid in the beds or *layings* in the creeks adjoining those rivers. The number of vessels immediately employed in the dredging for oysters is about 200, from twelve to forty or fifty tons burden each, employing from 400 to 500 men and boys. The quantity of oysters bred and taken in this county and consumed annually, mostly in London, is supposed to amount to 14,000 or 15,000 bushels. All the other fisheries connected with this part of the coast are stated to employ a capital supposed to amount to from L.60,000 to L.80,000.

Middlesex. This county, having no fishery of its own, but the very trifling one afforded by the Thames, is infinitely the greatest consumer of fish, and demands a larger supply than all the rest of the empire together. By a return of the cargoes of fish brought by water to the Billingsgate market, it appears that, on an average of six years ending 1785, the number of cargoes amounted to 1569, and of four years ending with 1803, the average was 2428; the average tonnage being about fifty, and the general average of fish in each about forty tons, which will give nearly 100,000 tons of fish. Supposing the quantity brought by land carriage to be one fifth of the other, the whole weight of fish brought to the London market would amount to the enormous quantity of 120,000 tons a year, which, supposing the capital and its environs to contain 1,200,000 inhabitants, would allow 200 pounds of fish annually to each individual; and, of course, a very considerable quantity must be dried or salted fish for exportation, if the returns be at all correct.

Kent, Sussex, Hampshire, and Dorset. In the *Agricultural Surveys* of these counties, little notice is taken of the fisheries; in the first they are not even mentioned. In Sussex, the produce of the ponds in carp, tench, and perch only are noticed; and even these, it would seem, are monopolized by a London fish-dealer. In the rivers of Hampshire the salmon fishery is carried on, but to no great extent. The little town of Hamble, situated on the shore of the Southampton water, has about twenty sail of well and other boats constantly employed in fishing, and which go as far as the Scilly Islands and the Land's End for lobsters, crabs, and craw-fish in the season. In the winter they dredge for oysters, and for about a month catch vast quantities of herrings round the Isle of Wight, the waters of which also afford employment in the whitings, plaice, prawns, shrimps, lobsters, and crabs, with which they abound. Southampton market is generally well supplied with all kinds of fish, and Portsmouth pretty well, but not equally so with the former place. The town of Poole in Dorset is deeply engaged in the Newfoundland fishery. Along the sea coast of all these counties, the mackerel fishery during the season, and the taking of the various kinds of white fish, especially soles and whitings for the London market, and the supply of the neighbouring towns, occupy a very considerable portion of the inhabitants of the former place.

Devonshire. The supply of salmon in the waters of Devon was formerly so abundant, that here too the farm servants found it necessary to stipulate that they should not be obliged to eat salmon more than twice a week; but the case of late years is widely altered, the fishery having fallen off so as to be of little or no importance. This is stated to be owing to a wasteful and improvident destruction of the species, by taking the young fish on their return seaward towards the end of the year; no less than a thousand having been taken in one week at Brightley on the river Taw, where, and at Umberleigh, it has been usual for the young salmon fry, or gravellers, to be given to the pigs.

The sea-fishery is conducted with a considerable degree of activity in this county, Brixham alone having no less than 100 sail of vessels employed in the fisheries. Soles, whitings, flounders, gurnet, john dories, and the red mullet, are caught in great abundance and of the finest quality, and sent off to London, Bath, and Bristol, also to Plymouth, Exeter, and the neighbouring towns; and when, in the summer season, the quantity taken is greater than can be disposed of, the fish are well cleaned, salted, and dried in the sun: thus prepared, they take the name of *buckhorn*, and are esteemed an excellent relish, much sought after in the navy, and also along the French coast.

Cornwall. In addition to the different kinds of fish which are taken off the coast of Devon, Cornwall has the advantage of an annual visit of vast shoals of pilchards, equally abundant, for the space they cover, with the shoals of herrings. The four principal ports from which the pilchard fishery is carried on are, Fowey, Falmouth, Penzance, and St Ives. At Polperro, which is perhaps the smallest establishment, upwards of forty boats and nearly 200 fishermen are engaged in the hook and line fishery; and the aggregate value of the fish taken is supposed to amount to L.5000 annually, most of which is distributed all over the country to the distance of thirty miles, by men and women carriers. The markets of Exeter and Bath, Plymouth, Liskeard, Tavistock, and other places, receive supplies from hence; and lobsters are delivered to the Southampton well-boats for London. The neighbouring poor are supplied almost all the year round with fresh and salted pilchards. Indeed the multitudes of these fish taken on the coast of Devonshire, as well as Cornwall, are enormous between the months of July and September inclusive, when the whole line of coast presents a scene of bustle and activity. The fish for foreign export and winter consumption are laid up on shore in large stacks or piles, with layers of salt between each row; here they are suffered to lie for twenty or thirty days, during which time a vast discharge of pickle mixed with blood and oil takes place, all of which is carefully caught in pits, and preserved for manure, which is eagerly purchased by the farmer and carried away in casks. It is said that every pilchard will dress and richly manure one square foot of ground. The fish are then carefully washed with sea-water, dried and packed in hogsheads, in which state they are sent abroad. The average value of pilchards taken in one year in Cornwall is supposed to be from L.50,000 to L.60,000.

The pilchard fishery has indeed been long of great importance to the inhabitants of the coast of Cornwall, the quantity taken by *seine* nets in some years having amounted to the enormous extent of 50,000 hogsheads; but it has not, on an average of the last fifteen years, exceeded half of that quantity. This, as before stated, is very much owing to the heavy duties imposed by the government of Naples; but the practice of driving the fish, and taking them by what are called drift nets, is considered as most injurious to the more important fishery by the seine.

The pilchard is supposed not to be a fish of passage, but to remain off the coast, in deep water, when not frequenting the bays. At such times they move about in large bodies of separate and distinct shoals, each shoal having, it is supposed, leading fish to direct them; indeed they are known to have a lively instinct of danger, and to leave the shore on the least interruption and noise. A few years ago, when an experimental squadron was manœuvring in the Channel, on exercising the great guns, the inhabitants of Cornwall complained that the pilchards had wholly disappeared, and requested that the practice of firing might be discontinued. It is this sensitiveness of the fish that makes the drift nets so particularly objectionable, the drivers following the shoals, and constantly interrupting their progress, diverting and dispersing the shoals, and preventing them from coming into shallow water.

The principal fishing station between Plymouth and Falmouth is Mevagissey, whence in the year 1818 about forty seines were sent out, which have since been reduced to about twenty, employing not more than about 330 men and 40 boys; but the employment given on shore to men, women, and children, is said to comprehend, directly and indirectly, nearly the whole population of the place. The original cost of each seine or concern is about L.1000 a float, and the capital on shore about L.500; so that the total outlay of the twenty seines will amount to L.30,000. Formerly these twenty seines would land in favourable seasons 10,000 hogsheads, which are said of late years scarcely to exceed 1000 hogsheads. The driving boats are stated to be about twenty-three, having two men, and in some instances two men and a boy, in each boat. The cost of a boat and nets may be from L.50 to L.100. The fish they catch are conveyed chiefly to the home market. Yet, insignificant as it appears to be, it is stated that the important branch of the fishery with the seine is fast sinking under the lawless proceedings of the drivers, which in the end must be its total ruin, unless it be protected by the government, or some more effective legislation. Why do none of the Cornish members take some steps to remedy this crying evil? Here there are no foreign competitors, but this valuable branch of the fisheries is impaired and threatened with destruction by the conflicting interests of our own countrymen.

Somerset. The salmon and herring fisheries of Porlock, Minehead, Watchet, and other places on the shores of the Bristol Channel, are stated to have been carried on to a considerable extent since the duty on salt used for curing fish for home consumption was removed; and the increase of the latter fishery has been the means, not only of furnishing employment during the winter for the seamen, who are engaged in the lime, stone, and culm trade during the summer, but of providing a cheap and wholesome food for the labouring class of inhabitants.

Fisheries of Wales.

The great extent of coast, washed by the sea, and the numerous fine streams and navigable rivers by which it is intersected, give to the principality of Wales the advantages of fisheries little if at all inferior to those in Scotland. In South Wales, Milford Haven, and its tributary streams, the Towy and its branches, the Laughor, the Teivy, and the Dovy, all navigable, abound with the finest salmon, sewin, trout, samlets, &c.; and the same kind of fish are equally plentiful in the twenty-two inferior streams, which fall into the sea on the coasts of the four maritime counties of Glamorgan, Caermarthen, Pembroke, and Cardigan. The value of the salmon sent to Bath and Bristol from Monmouth alone, the produce of the Wye, Usk, and Rumney, is said to exceed L.4000 annually, exclusively of what is consumed in the county. The sea affords them annual shoals of herrings, which, with potatoes, is one of the chief articles of sustenance for the poor. They first appear in the bay of Cardigan towards the middle of September, just as the harvest is finished. The other sea fish are cod, haddocks, whitings, skate, ray, turbot, plaice, flounders, soles, mullets, gurnards, mackerel, dories, shad, &c. Shell-fish of all kinds are most abundant, and in various parts of Milford Haven there are inexhaustible beds of oysters of superior excellence. Those of Tenby and other parts of the coast are of enormous size, but of inferior quality to those taken in Milford Haven.

It is worthy of remark, that the *sewin* is a fish peculiar to South Wales, and is not found in any river east of the Wye, or north of the Teivy, but frequents all the intermediate rivers, which they visit annually about the beginning of June, and continue in season till the end of August, weighing from one and a half to four or five pounds each. The samlet is a small fish about nine inches long, frequenting all the rivers in which salmon and trout are found; and it has been concluded, from the circumstance of a female samlet being utterly unknown, that they are the hybrid offspring of the female salmon and the male trout. As an article of food, they are excellent when fried, potted, or pickled.

In North Wales the sea fish are of the same description as those of the southern coast; and the herring fishery in the bay of Caernarvon is, perhaps, the most flourishing in all Wales; but the badness of the roads, and the distance by sea from any great market, check the demand for fish, and discourage the people from following the occupation. A good road from Caernarvon into Shropshire, to open a direct and speedy conveyance to the heart of England, where sea fish is scarcely known to nine tenths of the community, would be the means of increasing the demand for this palatable and wholesome food, of which the supply along the extensive coast of North Wales is inexhaustible.

Irish eries.

The sea coasts of Ireland are as abundant as, and perhaps more so, in every valuable species of fish, than those of Great Britain. Its numerous bays, creeks, inlets, lakes, and rivers, swarm with them. It is visited annually by vast shoals of herrings; and the banks near its shores are well stored with excellent cod, hake, and ling, equal in all respects to those caught upon the banks of Newfoundland. With the westerly winds, which may be reckoned to blow for nine months in the year, the produce of these fisheries might always be sent to ready markets at Bath, Bristol, Liverpool, and other great towns on the western and southern coasts of England; yet, either from indolence, want of inclination, or, which is more probable, want of capital, and most of all from want of proper regulations, the Irish have hitherto done little more than procure from their fisheries a scanty supply for the chief towns, and the families of those who are resident near the coast. It would seem, indeed, that the Irish have not much taste for a seafaring life, few of their young men volunteering for the navy, whilst they go in shoals into the army; and those few who follow the occupation of fishermen are so much prejudiced in favour of their own clumsy methods of proceeding, as to resist all attempts at improvement. It is stated by Mr Whately, in his *Hints for the Improvement of the Irish Fishery*, that, when the trammel net was attempted to be introduced, by which, in a couple of hours, more fish might be taken than with their hookers in a whole night, such was the prejudice against this new mode of fishing, that the crews of the hookers, alarmed at the supposed diminution of their profit by the increased supply, combined together along the whole coast, and destroyed the trammel nets wherever they were discovered. There is, however, a species of trall, not commonly made use of, which, according to the opinion of Mr Mitchell, is highly injurious to the Irish fisheries.

"The common method of fishing in this manner on the coast," says this author, "is with what they call a beam-trail, or trall, which consists of a large beam or pole, generally between twenty and thirty feet long, headed at both ends with large flat pieces of timber, which resemble the wheels of a common cart; except that, instead of being round, like them, they are rather semicircular, or resembling a heart cut in two, lengthways. They are shod, like the wheels of a cart, with iron. To this beam the trail net or bag is fixed, and at each end ropes are fastened, by the help of which the ground is entirely swept so clean, that I have been assured a fisherman will venture to throw his knife or any such small matter overboard, in thirty or forty fathom water, and readily take it up again; and thus the ground is swept clean for a considerable tract, at every put, as they call it, the boat commonly sailing a mile, or perhaps a league, before the bag and beam are hauled up.

"It has great inconveniences; for, 1*st*, it sweeps and tears away all the sea plants, moss, herring-grass, &c. which some fish feed on, making those species to seek elsewhere for food; 2*dly*, it disturbs and affrights the larger kinds of fish, as cod, ling, &c. in the same manner as if pursued by larger fish of prey; and, 3*dly*, which is worse than all, these beam nets, and others of the kind which are dragged along the ground, tear away, disturb, and blend up the spawn of many kinds of profitable fish, in a terrible manner; and often many hogsheads of their spawn are drawn up in the trall bags, in which may be distinctly seen several thousand embryos of young fish."

Under proper regulations, the Irish herring fishery would no doubt equal, if not exceed, that of North Britain. At present no pains are bestowed in the salting and gutting of the fish. In some parts of the coast they are thrown into holes dug in the earth, and there salted, whence they are sent in bulk to Cork and other places, to be put into barrels. Loch Swilly is one of the principal bays for the herring fishery. The salmon fisheries in the north of Ireland might be rendered very valuable. That of Coleraine is, perhaps, the most productive; from five hundred to nearly a thousand fish being sometimes taken at a single draught. They are mostly pickled for exportation.

of M

If the information be correct which is stated by Mr Fraser, in *A Letter to the Right Honourable Charles Abbot*, nothing can more strongly exemplify the beneficial effects arising from the free use of salt without being subject to bonds, pains, or penalties, than those derived from the privilege granted by parliament to the inhabitants of the Isle of Man, to import salt from England duty free, not only for curing fish, but for all other domestic purposes. "In the year 1784," says Mr Fraser, "I had the honour to be appointed by the Treasury to make an inquiry into the state of the revenue and fisheries of that island. I found that, at that period, without bounties on their boats, or the tonnage of their fishing smacks, or any premiums other than the free use of salt, they carried on a most extensive fishery, which employed 2500 seamen. In the absence of the herrings, the fishermen supplied the consumption of the island in great abundance with white fish; the agriculture was greatly increased, and the population consisted of 30,000 souls, having nearly doubled the number of its inhabitants in fifteen years." It further appears, from the *Report of the Committee of the House of Commons for the Fisheries in* 1798, that their boats had increased, both in number and size; that from a burden of ten or twelve tons, they had now advanced from sixteen to twenty-two tons, of which the number exceeded 350, each employing seven or eight men; that they had, besides, from forty to fifty fishing smacks from twenty to forty tons each, the whole employing upwards of 3000 seamen, which were then equal to the number of men and boys employed in the whole of the buss fishery of Scotland, supported by bounties to the extent of L.20,000 a year.

Forei
fisheri

Newfound-
land fish-
eries.

The fish which we have said to be next in importance to the herring in point of value, is perhaps not inferior to it in point of numbers. Like it, too, the cod is supposed to be migratory, though confined chiefly within the limits of 44° or 45°, and 68° or 70° of latitude, and is found generally on banks covered with a considerable depth of water; and the deeper the water the better is the quality of the fish. It is for this reason that the great Banks of Newfoundland, those near Ireland, the coast of Norway, the Orkney and the Zetland Islands, and other banks in the North Sea, the principal of which are the Wellbank, the Doggerbank, and the Broad Forties, are resorted to as the most favourable spots for the cod fishery. Of all these, however, the Banks of Newfoundland are most esteemed, and are, in consequence, the general fishing grounds of all European nations, more especially the English and French. Formerly the Portuguese were the great fishers on these banks, and had their establishments on shore; but their fishery, like their commerce, fell with the decline of their naval power, and they are now content to buy their fish in their own ports, brought thither by ships belonging to foreigners. The Dutch have also for many years abandoned a fishery which they found less profitable than that nearer home. Indeed, so jealous were we once of the Dutch fishing on the Banks of Newfoundland, that Sir William Menson, in his treatise of the fishery, cautions the government to beware of letting them in; "for," says he, "they are like a serpent that never stings so deadly as when it bites without hissing." The French, by the treaty of 1763 with Great Britain, were limited in their fisheries to the neighbourhood of the small islands of St Pierre and Miquelon; and the Spaniards, by the same treaty, consented to abandon the Newfoundland fisheries altogether.

Since that time, however, a more formidable rival to the British fishery has started up in that of the Americans, who have latterly prosecuted the cod fishery with great vigour, and with advantages which the English, even with the possession of Newfoundland, are unable to command; owing, in a great degree, to the regulations by which this ancient possession of the British empire has till very lately been governed.

In a pamphlet entitled *Considerations on the Expediency of Adopting Certain Measures for the Encouragement or Extension of the Newfoundland Fishery*, supposed to have been written by the Secretary of Lord Gambier, when governor of that island, it is stated, that in the year 1805, the number of vessels employed in the American fishery amounted to about 1500, carrying about 10,000 men, and that the quantity of fish caught by them amounted to 800,000 or 900,000 quintals; whilst the whole produce of the British Newfoundland fishery of that year did not exceed 500,000 quintals, and that the number of vessels and men employed did not amount to one half of that employed by the Americans.

The causes assigned for this increasing success on the one hand, and falling off on the other, are as follow: The New England fishery, in all its branches, is carried on by shares, each man having a proportion of his own catch, and few or none being hired as servants on wages. By this mode the fisherman's interest being proportioned to his industry, he is prompted to labour by the most powerful incentive. The American fishermen are remarkable for their activity and enterprise, and not less so for their sobriety and frugality; and, in order to be as independent as possible of the owner of the vessel, each fisherman victuals himself, and the crew take it in turns to manage and cater for the rest. It is hardly necessary to add, that men, provisions, and every other article of outfit, are procured upon much better terms in the United States than in Great Britain. But the English fishermen must not only lay in a large stock of provisions out and home at a dear rate, but must also carry out with them a number of persons to assist in the fishery, who, consequently, eat the bread of idleness on the passage out and home; for the laws by which the colony was held were such as almost to forbid residency, and those who did reside had no power of internal legislation; they were restrained from erecting the necessary dwellings for themselves and their servants; they were prohibited from enclosing and cultivating the land, beyond the planting of a few potatoes; and from the importation of provisions from the United States, excepting only on such conditions as were not calculated to afford the residents much relief. "From a system," says the author of the pamphlet above mentioned, "the first object of which is to withhold that principle of internal legislation, which is acknowledged to be indispensable to the good government of every community, which restrains the building of comfortable dwellings in a climate exposed to the most inclement winter, which prohibits the cultivation of the soil for food, and restricts the importation of it from the only market to which the inhabitants have the power to go,—from such a system it is not surprising that the inhabitants of Newfoundland are not able to maintain a competition against the American fishermen."

During the late war, however, when France was completely driven out of her fisheries in the Gulf of St Lawrence, and the islands of St Pierre and Miquelon, the British and the resident fisheries about equalled, in the amount of fish taken, that of the Americans in the same quarter, who employed, in the year 1812, about 1500 vessels carrying each ten men, making, in the aggregate, the enormous number of 15,000 men employed in this branch of trade alone. The English merchants of London and Poole complain, and not without apparent good grounds, of the extraordinary privileges which America enjoyed at Newfoundland, in being permitted to cure and dry her fish on shore; which privileges, granted no doubt on an expectation that such a liberal proceeding would have paved the way to a reciprocal friendly conduct on her part, became a source of gross abuses and of unwarrantable claims. By the assembling together of numerous fleets, they interrupted the occupations of our residents; they destroyed their nets, enticed away their servants, smuggled into the colony coffee, tea, spirits, tobacco, India goods, and other articles of contraband, undersold the inhabitants in stores and provisions, and added insulting and abusive language to their manifold injuries.

Since the conclusion of the war, the United States have been re-admitted, by a convention, to all their former privileges of curing and drying their fish on the unsettled bays, harbours, and creeks of Nova Scotia, Labrador, and Newfoundland; but under certain modifications, which it is hoped will prevent those abuses that existed in a flagrant degree previously to the war. The Great Bank, owing to its distance from the shores of Newfoundland, is of course free to all the world; but the fishery can only be successfully carried on by a constant and uninterrupted communication with the shore, and the nearer to the shore that the fish are taken, the more advantageous is it to the fishermen. The Americans, being restrained from fishing within certain limits, and having the privilege of curing and drying their fish only at certain spots on the shore, labour under a comparative disadvantage with us in this respect, which serves to balance the advantage they possess over us in others. Under this convention, the fishermen of the United States are at liberty to take fish, in common with the subjects of his Britannic Majesty, on that part of the southern coast of Newfoundland which extends from Cape Ray to the Rameau Islands, from Cape Ray to the Quirpon Islands, on the shores of the Magdalen Islands, and also on the coasts, bays, harbours, and creeks, from Mount Joly, on the southern coast of Labrador, to and through the strait of Bellisle, and thence northerly indefinitely along the coast; and they are at liberty also to dry and cure fish in any of the unsettled bays, harbours, and creeks of the southern part of the coast of Newfoundland, and of the coast of Labrador; but as soon as the same, or any portion thereof, shall be *settled*, they are no longer at liberty to dry and cure fish at such portion, without a previous agreement with the inhabitants or proprietors; and, in consideration of these privileges, the United States renounce, on their part, any liberty heretofore enjoyed or claimed by their subjects, to take, dry, or cure fish, on or within *three marine miles* of any of the coasts, bays, creeks, or harbours of his Britannic Majesty's dominions in America, not included within the above-mentioned limits; but they may be admitted to such bays and harbours, for the purpose of wooding, watering, or repairing damages only. The merchants of Poole, and others concerned in the fishery, complain of this treaty; but it appears to be well calculated to prevent those disputes and abuses which before existed, and which would probably have interrupted the harmony so desirable to be preserved between the two nations.

The importance of the fisheries on the Banks of Newfoundland, on the coast of Labrador, in the Gulf of St Lawrence, and the neighbouring islands, may be conceived, from a memorial of the committee of merchants trading to Newfoundland, addressed, in 1814, to Lord Liverpool, in which it is stated that the catch of the French was generally estimated, at the least, at 300,000 quintals; that the Americans had reached, in 1811, nearly 1,000,000 quintals, besides fish-oil and other articles, the produce of the sea; and that the English fishery, during the American war, had increased to a degree equal to the most sanguine expectations; the export of dried cod alone, for the year 1813, having amounted to 946,102 quintals, which exceeded the shipment of the preceding year by nearly 300,000 quintals, or one third of the catch of the whole fishery, with a proportionate increase in cod-oil, seal-skins, seal-oil, salmon, &c. amounting in value to above L.1,500,000 sterling; employing in its transport to different markets at least 75,000 tons of British shipping, and 5000 seamen, independently of the persons actually employed in catching and curing the fish; and returning to England upwards of L.2,000,000 sterling.

These advantages, however, can scarcely be supposed to continue since the re-admission of the French and Americans, both of whom, it is to be feared, will be able to undersell our fishermen in the foreign markets; the former from a considerable bounty being given by government on the fish caught and cured on the Banks of Newfoundland, and the latter from their nearness to the fishing grounds, and cheapness of the outfit. It has indeed been questioned by political economists, whether it would not be more advantageous to the national interests, if the capital employed in the distant possession of Newfoundland, and the fisheries contiguous to it, were engaged wholly in the fishery on the banks of our own seas, and those of Iceland and the coast of Norway, which are so much nearer home. Newfoundland, however, in spite of all the restrictions imposed upon it, has risen into a colony of too much importance to be abandoned; and its growing prosperity depends so much (it may be said indeed solely) on the fishery, that the residents, with the assistance of America, will always be able to carry it on independently of England. Much of late has in fact been done to improve the condition of the colonists, and more will be required. Among other things, a resident governor has been appointed, so that the inhabitants are not left for a great portion of the year, as heretofore, to administer justice among themselves, which was usually done in his absence by a surrogate, with a salary of L.60 a year, and magistrates, whose occupations are in some way or other connected with the fishery.

The nature and value of the exports from Newfoundland will be seen by the following table:

mate of the Value of the Exports from Newfoundland between the 11*th of October* 1801 *and the* 10*th of October* 1802; *distinguishing the Countries to which they were sent, and the remittances proceeding therefrom to Great Britain.*

But the following statement, taken from official documents, as the returns of the two years ending the 10th October 1814 and 1815, will show the advanced and advancing state of the fisheries of Newfoundland and of the colony.

In 1814.		In 1815.		Difference in one Year.
				Increase.
1. Number of fishing ships, European and island bankers, ships from Nova Scotia, &c. the West India and stationary vessels	892	Number of the same description	1,036	144
2. Burthen of the above-mentioned ships	107,998 tons.	Of the same	127,582	19,584
3. Number of men belonging to them	6,966	Number of the same	7,981	1,014
4. Number of boats kept by the fishing ships, bye-boatmen and inhabitants	3,241	Number of the same	3,518	277
5. Number of men employed in the fishery and trade in ships and boats, and as shoremen	19,295	Number of the same	22,167	2,872
6. Quintals of fish caught and cured by the fishing ships, bankers, and boats	865,132	The same	866,580	1,448
7. Exported to Spain, Portugal, and Italy, British Europe, the West Indies, British America, and the Brazils	947,811	The same	1,180,661	232,850
8. Tierces of salmon cured and sent to British and foreign markets	3,425	The same	3,752	327
9. Tuns of train oil made by the fishing ships	4,126	The same	4,298	172
10. The number of seal-skins taken	110,275	The same	121,182	11,007
11. Tuns of seal oil made	1,263	The same	1,397	134

The price of cod fish is, per quintal, from 15s. to 25s.; of salmon, from 65s. to 80s. the tierce; of train oil, from L.26 to L.34 the tun, and seal oil generally about L.36 the tun. In 1814 the number of passengers who went over from England, Ireland, and Jersey, amounted to 2800; in 1815 they were 6735. In 1814 the population of residents amounted to 35,952, and in 1815 to 40,568. In 1814 the summer inhabitants were 45,718, and in 1815 they were 55,284. The number of houses on the whole island was about 5000, and the number of acres under cultivation about 6000.

Northern whale fishery.

If we are to credit the information which Alfred is said to have received from Octer, the Norwegians were engaged in the whale fishery as early as the year 890. The story, however, is not very probable. The first people known to have carried it on as a regular occupation were the Biscayans, who, when the English first embarked in this fishery, towards the end of the sixteenth or beginning of the seventeenth century, were always engaged as part of the crew. It continued to be carried on by the Russian and the East India Company for some years, but with no great success, though sufficient to induce the Dutch to attempt it. After them came the Danes, the Hamburgers, and the French, all of whom were finally driven out, or nearly so, by the Dutch. At this time the whales were so plentiful in all the bays of Spitzbergen, that the practice then was to boil the oil on shore; but when, in process of time, these large fish became more scarce, or were scared from the shore, the fishery was carried on at a distance from the land, when it was found necessary to bring home the solid blubber in casks. This circumstance was a further discouragement to the English merchants, who, for more than a century, relinquished the whale fishery altogether. The South Sea Company, however, revived it in the early part of the eighteenth century, when parliament granted a bounty of 20s. per ton on all British ships of 200 tons and upwards, which was afterwards increased to 40s. per ton. This, however, by the 26th Geo. III. was again reduced to 30s.; but several encouragements were added for the prosecution of the whale fishery by able and expert seamen. The harpooners, the line-managers, and the boat-steerers, were not only protected from impress during the voyage, but were allowed to engage in the coal and coasting trade unmolested in the winter months, with other privileges granted by that and subsequent acts.

The decline of the Dutch whale fishery kept pace with the decline of their herring fishery, and, from the same cause, the decline of their maritime power, which had reciprocally supported each other. The English now began to carry on the fishery with great vigour on both sides of Greenland, so as to make it an object of great national importance, both as a nursery for excellent seamen, and as a source of public wealth. Upon the termination of the late war, the owners of ships employed in the northern whale fishery, alarmed by the apprehension of the Dutch and French reviving the fishery, but more so at the opening of the ports on the Continent, put forth a statement of the amount and extent of the fishery, from which it would appear that 7500 men and boys are employed in it as sailors; that, by act of parliament, the owners are required to take six apprentices for each ship of 300 tons, by which about 900 youths are constantly training for the future service of the country, and that about 200 of them complete the term of their servitude every year, when such as are not boat-steerers, harpooners, or line-managers, become liable to serve in the navy; that not less than 300 men are also taken annually from employments on land, or from the river trade, most of whom, after two years, are competent to serve in his majesty's navy; who, with the apprentices and unprotected seamen employed, make a total of 4000 effective men subject to impressment.

It is further stated by the owners, that at the termination of the war, no less than 148 valuable ships, comprising 50,000 tons, and engaging a capital of L.2,000,000, were employed in the Greenland and Davis' Straits fishery; that the provisions for the voyage amount to about L.600 for each ship, forming a total of L.90,000, wholly furnished from our own markets, affording encouragement to agriculture, as well as to the various descriptions of tradesmen through whose hands the provisions are supplied; that the whole produce, therefore, of the fishery may be considered as gain to the country.

As, however, foreign ships may be sent to the fishery on more moderate terms than the English can supply theirs, and as the king of the Netherlands has offered considerable bounties to ships proceeding to the northern fisheries, all hope appears to be cut off that Englishmen will ever be again permitted to contribute to the supply of foreign markets with whale oil, but must in future look to the consumption of Great Britain alone. It is therefore suggested by the shipowners as some relief, that the enormous quantity of foreign rape-seed, which has recently been imported into this country nearly duty-free, should be checked; and that, by laying a sufficient duty on the importation of this article, the protection of government would be beneficially extended at once to the encouragement of the British agriculturist and the relief of the Greenland trader. No reasonable objection, it is stated, can be made to such a measure, unless from a mistaken apprehension with regard to its effects on the price of woollen cloths, which is so inconsiderable that a duty of L.12 per last on foreign rape-seed would not occasion an advance of more than about one farthing and a half per yard on narrow cloths; and that in fine cloths Gallipol oil alone is used. This appears to be reasonable enough; but the owners of the whale-fishing ships had another and a more formidable rival in the market in the lighting of the streets of London and other great towns with gas. It was stated, that for every three parishes in the metropolis thus lighted, five whole ships would be thrown out of employment; and that if all the parishes in London, Westminster, and Southwark, should be so lighted, it must entirely put an end to a trade which employs 10,000 seamen, 2000 apprentices, and 2000 landsmen, training constantly to the sea, and which affords occupation to about 100,000 individuals. The Gas Company say, on the other hand, that the expenditure of coal will amply compensate, in a national point of view, for any loss the Greenland trade may sustain, by the additional quantity of shipping employed in bringing the coal to the metropolis. This, however, is an exaggerated statement; but as whale-oil is now employed for so many more purposes than formerly, and even in the manufacture of gas, the lighting of the streets, even if general, will probably not injure the fishery to any great extent; though the lighting of the shops and private houses, should the practice become general, must seriously injure the South Sea fishery, as sperm was very commonly used for domestic purposes.

The state of the northern whale fishery will be seen from the following account of the number of fish and produce of oil brought by the ships of the several ports of Great Britain from the Greenland and Davis' Straits fishery, in the year 1814:

Ships.		Fish.	Oil.
58	Hull	697	7326
20	London	367	2981
1	Lynn	25	187
1	Grimsby	7	85
8	Whitby	172	1381
5	Newcastle	49	628
2	Berwick	16	178
10	Leith	73	1021
1	Kirkaldy	7	100
8	Dundee	61	955
3	Montrose	47	306
2	Liverpool	43	437
13	Aberdeen	178	1733
7	Peterhead	164	1390
2	Banff	30	245
1	Kirkwall	10	120
1	Greenock	35	245
143	Total	1981	19,408

143 ships, at 50 men to each ship, give 7150 as the number of men employed annually in the northern whale fishery.

19,408 Tuns of oil, at L.38	L 737,504	0	0
647 Ditto whale-bone, the produce of 1981 fish, at L.80 per ton	51,760	0	0
Total amount of the produce of the northern whale fishery in the year 1814	L.789,264	0	0

The statutes of 35 Geo. III. c. 92, and 42 Geo. III. c. 18, regulate the proceedings, and prescribe the conditions on which premiums of L.100 to L.400 may be claimed by each of sixteen ships employed in this fishery. Though less important, in a national point of view, than the northern whale fishery, the number of ships and seamen employed in it are very considerable. They are fitted out mostly from London, and amounted, in the year 1815, to 107 ships, comprising 32,100 tons, and manned with about 3210 seamen, and their return cargoes were calculated to be worth about L.1,070,000 sterling.

The returns of the two fisheries, then, will stand thus:

	Ships.	Men.	Value.
In the northern fishery	143	7150	L.789,264
In the southern ditto	107	3210	1,070,000
Total	250	10,360	L.1,859,264

These statements of the productive value of the foreign British fisheries may probably approach pretty nearly to the truth; but the reports of the home fisheries are too vague to afford any thing like an accurate estimate. If we should take the 120,000 tons of fish said to be imported annually into the metropolis, at the low average rate of threepence a pound, and allow for the rest of the consumption in the British empire only one half the quantity consumed in and exported from the capital, and half a million for the export produce of the herring and cod and ling fishery, we shall have the productive value of the whole as under:

The Greenland and South Sea fisheries	L.1,800,000
The Newfoundland fishery	1,500,000
The herring, cod, and ling ditto for exportation	500,000
The consumption of London and re-exportation	3,000,000
Ditto of the rest of Great Britain	1,500,000
	L.8,300,000

As to the number of seamen, landmen, and boys employed in the fisheries, that is, *on the water*, they may be reckoned at about 120,000.

Pearl Fishery. See *Pearl*, MOLLUSCA, *Index*.

Whale Fishery. See *Balæna*, MAMMALIA, *Index*.

FISHGUARD, a market-town of Pembrokeshire, in South Wales, within the hundred of Komyss, 151 miles from London. It is situated on the shore, at the spot where the river Gwaine falls into the sea. It is governed by a mayor and corporate body. The trade is but trifling, but there is a well-supplied market on Friday. A corps of 1200 French troops, composed chiefly of enlisted felons, landed here in 1797, but were speedily made prisoners by the local volunteers. The population in 1801 amounted to 1503, in 1811 to 1572, in 1821 to 1837, and in 1831 to 1990.

FISHING, in general, is the art of catching fish, whether by means of nets, spears, or the line and hook. See ANGLING and FISHERIES.

FISSURES, in *Geology*, certain interruptions, which divide the several strata of which the body of our globe is composed, in a horizontal or parallel manner.

Fissure of the Bones, in *Surgery*, is when they are divided either transversely or longitudinally, not quite through, but cracked like glass, by any external force.

FISTULA, in the ancient music, a wind instrument resembling our flute or flageolet.

The principal wind instruments of the ancients were the *tibia* and the *fistula*. But how they were constituted, in what they differed, or how they were played upon, does not appear; indeed all that we know is, that the *fistula* was at first made of reeds, and afterwards of other matters. Some had holes, others none; some again were single pipes, others a combination of these; as, for instance, the *syringa* of Pan.

FISTULA, in *Surgery*, a deep, narrow, and callous ulcer, arising generally from abscesses. It differs from *sinus* in being callous, which the latter is not.

FITCHES, in *Husbandry*, a sort of pulse, more generally known by the name of *chick-pea*. Fitches are cultivated either for the purpose of feeding cattle or improving the land. They are a wholesome and nourishing food, whether given in the straw or thrashed out. When sown only to improve the soil, they are ploughed in just as they begin to blossom, by which means a tough clay soil is much enriched.

FITCHET, a name used in some places for the weasel, which is also called the *foumart*.

FITCHY, in *Heraldry* (from the French *fiehé*, fixed), a term applied to a cross when the lower branch ends in a sharp point. The origin of this device is supposed to be, that the primitive Christians were accustomed to carry about crosses with them wherever they went; and when they stopped at any place on a journey, they fixed these portable crosses in the ground for the sake of devotion.

FITERO, a town of Spain, in the province of Navarre. It is situated on the banks of the Alhama, which, though a river of short course, is highly beneficial, by its irrigating capabilities, to the country through which it passes. The monastery of Fitero is very richly endowed; and the town, which contains 3500 inhabitants, as well as the land around it, is the property of that establishment. The whole of the people are employed in the cultivation of hemp, and in the consequent manufactures of that article. There are some warm mineral springs, which are resorted to for the cure of several complaints, and which attain to the heat of thirty-six degrees Reaumur.

FITZHERBERT, SIR ANTHONY, a learned lawyer in the reign of Henry VIII. was descended from an ancient family, and born at Norbury in Derbyshire, but in what year is not known. After receiving the rudiments of his education in the country, he was sent to Oxford, on leaving which he entered himself in one of the inns of court, and appears in due time to have been called to the bar. By talents and diligence, united with judgment, he soon distinguished himself in his profession, and in 1511 he became a serjeant at law. In 1516 he received the honour of knighthood, and the year after was made one of the king's counsel. And in 1523 he was raised to the bench as a puisne judge of the court of common pleas, in which honourable station he spent the remainder of his life. Fitzherbert was deservedly respected for his ability and integrity as a judge; and, at a time when judicial independence was a rare virtue on the bench, he opposed the court in some of its favourite projects, particularly regarding the alienation of church lands. He died on the 27th of May 1538, and was buried in the parish church of Norbury, the place of his birth. The works of this learned lawyer are, 1. The Grand Abridgment collected by that most reverend judge Mr Anthony Fitzherbert, lately conferred with his own manuscript corrected by himself, together with the references of the cases to the books, by which they may be easily found, printed in folio by Rynson in 1514, by Wynken de Worde in 1516, and again in 1577; 2. The Office and Authority of Justices of Peace, 1538, but often reprinted, the last edition being dated 1617; 3. The Office of Sheriffs, Bailiffs of Liberties, Escheators, Constables, Coroners, and others, 1538; 4. Of the Diversity of Courts, 1529; 5. The New *Natura Brevium*, 1534, to which, in the last edition, published in 1794, 2 vols. 8vo, is added a commentary supposed to have been written by Chief-Justice Hale, with notes, references, and an enlarged index; 6. Of the Surveying of Lands, 1539; 7. The Book of Husbandry, 1534, reprinted several times in the reigns of Mary and Elizabeth. Of these works, five, in the order in which they are here enumerated, were, with the exception of part of the second, originally written in French.

FITZSTEPHEN, William, an English monastic historian of the twelfth century, and author of the earliest description extant of London, was of Norman extraction, but born of respectable parents in the city of London. Being a monk of Canterbury, he attracted the notice of Archbishop Becket, who made him one of his clerks, received him as an inmate into his family, and employed him in various capacities. He was remembrancer in the archbishop's exchequer, a subdeacon in his chapel when he officiated, a reader of bills and petitions when his grace sat to hear and determine causes, and sometimes an advocate before the ecclesiastical court, when he was desired to perform that office. He was also present with Becket at Northampton, when the archbishop was forsaken by his suffragans, and an eye-witness of his sacrilegious murder at Canterbury, one of the foulest deeds of an age fertile in crimes. This worthy monk is supposed to have died in the year 1191. His *Description of the City of London*, which seems to have been written between the years 1170 and 1182, contains, after Doomsday-Book, the earliest account we have of the metropolis; and it may be doubted whether any other nation of Europe can produce a description of its capital, or of one of its principal cities, written at so remote a period as the twelfth century. The first edition appeared in the shape of a translation inserted in Stowe's *Survey of London*; but as this was found to be in many respects inaccurate, and had, besides, become obsolete, Dr Pegge published a more correct translation, with notes and a preliminary dissertation, 1772, in 4to. Fitzstephen was a person of great learning for his age. He appears to have been tolerably versed in Horace, Virgil, Sallust, Ovid, Lucan, Persius, and other Latin classics; and he had even looked into Plato and some other of the Greek writers. His credulity was a failing less imputable to the individual than to the times in which he lived.

FIUME, a circle in the Austrian province of Trieste, extending over 1364 square miles, containing thirty-four cities and towns, and 193 villages, with 24,930 houses, and 131,484 inhabitants. The principal products are wine, olives, fruit, and silk. The capital is a sea-port situated on the Gulf of Quarnaro. It consists of two long parallel streets on the shore, and others connecting them, and contains 743 houses and 7576 inhabitants, chiefly employed in fishing or in trade, which consists in the productions of the surrounding district. The harbour is good, and the situation as favourable for the trade with Hungary as Trieste is for that of the other Austrian states. Long. 14. 20. 10. E. Lat. 45. 20. 16. N.

FIXATION, in *Chemistry*, the rendering of any volatile substance fixed, so as not to fly off or evaporate upon being exposed to a great heat.

FIXED BODIES are those which sustain a considerable degree of heat without evaporating, or losing any of their weight. Some of the most fixed bodies are diamonds, gold, &c.

FIXITY, or Fixedness, in *Chemistry*, is in a peculiar manner used for the affection opposite to volatility; in other words, it is the property by which bodies sustain the action of the fire, without being dissipated in fumes.

FIXLMILLNER, Placidus, a learned astronomer, was born at Achleuthen, near Linz, in Austria, on the 28th of May 1721. He received the rudiments of his education in the monastery of Kremsmunster, of which his uncle Alexander was abbot; afterwards went to Salzburg, where he studied a regular course of philosophy, but turned his attention particularly to the mathematics. In 1737, he was admitted as a novice into the Benedictine monastery, Kremsmunster, and the next year he took the solemn vow in presence of the abbot. After being two years in this monastery, during which time he devoted every leisure hour to the study of mathematics and philosophy, he returned to Salzburg to finish his studies in theology and jurisprudence, and at the same time acquired a competent knowledge of the oriental and modern languages, besides history and antiquities. In 1745, he obtained the degree of doctor in divinity, after which he received priest's orders in his own monastery, and was created professor of ecclesiastical law, which office he held during forty years, discharging its duties until within a few days of his death. He was also chosen as dean of the higher schools, and regent of the young nobility, offices which he retained during his life.

Fixlmillner wrote a commentary on the *Jus Canonicum*, but this work was never published. By the entreaties of his friends, he was induced to publish his *Reipublicæ sacræ Origines divinæ, seu Ecclesiæ Christi exterior junctura, imperium, et hierarchia, ex primigenia ejus institutione eruta et demonstrata*. But it was his knowledge of astronomy which rendered him truly illustrious. His uncle Alexander fitted up an apartment for containing the instruments necessary for the pursuit of mathematical knowledge; and he also erected an observatory, which was begun in 1748, and completed in 1758, under the direction of Anselm Dering of Emsdorf, a celebrated architect. Whilst the observatory was building, Fixlmillner led a life of retirement and severe study, his favourite pursuit during this time being astronomy. When the edifice was finished, Dobler, a mathematician of some note, was appointed first astronomer; but the successors of his uncle the abbot having discovered Fixlmillner's extensive mathematical knowledge, made him an offer of the astronomical department, and the sole direction of the observatory; and this place he accepted in the year 1762, at the same time retaining his chair as professor of ecclesiastical law. He was not yet master of the learning which practical astronomy requires; but to remedy this defect he perused attentively Lalande's *Exposition du Calcul Astronomique*, soon after which he obtained the large astronomical work of the same author, and in 1766 published his *Meridianus Speculæ Astronomicæ Cremifanensis*, Steyer, 4to, by which he acquired considerable reputation. Ten years after this period he gave the world his *Decennium Astronomicum*, Steyer, 4to, containing many curious and important particulars respecting the theory and practice of astronomy. His *Acta Astronomica Cremifanensia*, Steyer, 1791, 4to, which did not appear till after his decease, still further increased his astronomical reputation; and he was, besides, a large contributor to many periodical publications in different countries.

He made and collected a great number of observations on the planet Mercury, the importance of which was publicly acknowledged by Lalande, as they greatly assisted him in constructing his tables of that planet. Fixlmillner was one of the first astronomers who calculated the orbit of the new planet Uranus (*Georgium Sidus*), his tables respecting which will be found in the Berlin Almanack for 1789. He also proved the truth of what had formerly been conjectured, that the thirty-fourth star of Taurus, which Flamsteed observed in 1690, was the new planet. It may be said of most philosophers, that they observe a great deal and calculate little; but the conduct of Fixlmillner was exactly the reverse. He turned his attention more than any of his predecessors to the solar spots, which he observed in the years 1767, 1776, 1777, 1778, and 1782, and from which he deduced important inferences respecting the revolution of the sun on his axis.

Fixlmillner had a genius singularly adapted for the study of mechanics, by which he was enabled to invent a new micrometer, and a machine for grinding concentric circles. As he resided in the country, he was in a great measure deprived of literary assistance; but his indefatigable zeal, diligence, and perseverance more than supplied the want of such aid. He was but little subject to the influence of the stronger passions. Like the laws of nature, which it was his chief delight to study, he was simple, uniform, and constant; and by the mildness and integrity of his character, he acquired the love and esteem of mankind. His high reputation never inspired him with vanity, and he rather wished to conceal than to propagate what had been written in his praise. His health having been very much impaired by his intense application, he terminated his earthly career on the 27th August 1791, in the seventy-first year of his age.

FLACCUS, Caius Valerius, an ancient Latin poet, of whom personally but little is known. He is supposed to have been born at *Setia*, a town of Campania, now Sezzo, whence he has derived the surname of Setinus. But Martial, his contemporary and friend, seems to intimate that he was a native of Padua, or at least lived there. He died when he was about thirty years of age, in the year 93 or 94 of our era, before he had put the finishing hand to the poem on which his reputation entirely rests. The subject which he selected as deserving of celebration was the history of the Argonautic expedition; but of the ten books into which he intended to divide it, he lived only to compose seven and part of the eighth. This poem, which is addressed to the emperor Vespasian, whom the poet compliments on account of his conquest of Judæa, whilst Domitian is at the same time praised for his poetical talents, is an imitation rather than a translation of the Argonautics of Apollonius; and Flaccus has evidently been most successful in those parts where he had not the Greek poet immediately in his view. The model upon which he formed himself was Virgil; and, notwithstanding Horace's sneer at the *servum pecus*, it is surprising how closely the imitator sometimes approaches to the great original. Quintilian's opinion of his merit may be easily gathered from the brief but expressive eulogium, *Multum in Valerio Flacco nuper amisimus.* The best editions of this poet are that of Nicolas Heinsius, published at Amsterdam, 1680, in 8vo, reprinted of the same size in 1702; and that *cum notis integris variorum et Petri Burmanni*, which appeared at Leyden, 1724, in 4to. It is proper to add, that Baptista Pius, an Italian poet, completed the eighth book of the *Argonautics*, which Flaccus had left unfinished, and added two more from Apollonius; a supplement which was first printed by Aldus in 1523, and which has been subjoined to most, if not all, of the subsequent editions. (Vossius *de Poet. Lat.*; Fabricius, *Bibl. Lat.*; and Moreri.)

FLAGS, in the army, are small banners of distinction stuck in the baggage waggons, to distinguish the baggage of one brigade or battalion from that of another, in order that they may be marshalled by the waggon-master-general, so as to avoid the confusion that might otherwise ensue.

Flag, in nautical affairs, a banner or standard, by which an admiral is distinguished at sea; also the colours by which one nation is distinguished from another.

In the British navy flags are either red, white, or blue, and are displayed from the top of the main-mast, fore-mast, or mizen-mast, according to the rank of the admiral. When a flag is displayed from the staff on the main-mast, the officer distinguished thereby is known to be an admiral; when from the fore-mast, a vice-admiral; and when from the mizen-mast, a rear-admiral.

The first flag in Great Britain is the royal standard, which is only to be hoisted when the king or queen is on board the vessel; the second is that of the anchor of hope, which characterizes the lord high admiral, or lords commissioners of the admiralty; and the third is the union flag, in which the crosses of St George and St Andrew are blended together. This last is appropriated to the admiral of the fleet, who is the first naval officer under the lord high admiral.

The next flag after the union is that of the white squadron at the main-mast head; and the last which characterizes an admiral is the blue, also at the main-mast head. For a vice-admiral, the first flag is the red, the second the white, the third the blue, at the flag-staff on the fore-mast. The same order proceeds with regard to the rear-admirals, whose flags are hoisted on the top of the mizen-mast. The lowest flag in our navy is accordingly the blue on the mizen-mast.

To Lower or Strike the Flag, in the navy, is to pull it down upon the cap, or to take it in, as a token of the respect due from all ships or fleets to those which are undeniably their superiors. To lower or strike the flag in an engagement is a sign of submission or surrender.

The method of leading a ship in triumph is to attach the flags to the shrouds, or the gallery, in the hind part of the ship, letting them hang down towards the water, and to tow the vessels by the stern. Livy relates that this was the mode in which the Romans used those of Carthage.

To Heave out the Flag, is to display or put abroad the flag.

To Hang out the White Flag, is to ask quarter; or, when a vessel has arrived on a coast, it shows that it has no hostile intention, but comes to trade, or the like. The red flag is a sign of defiance and battle.

Flag-Officers are those who command the several squadrons of a fleet; such as the admirals, vice-admirals, and rear-admirals. The flag-officers in our pay are the admiral, vice-admiral, and rear-admiral, of the white, red, and blue. See Navy.

FLAGELLANTES, a set of wild fanatics who chastised and disciplined themselves in public by means of the lash. The sect of the Flagellantes took its rise in Italy in the year 1260; its author was one Rainier, a hermit, and it was thence propagated throughout almost all the countries of Europe. The formation of this sect was in all probability merely the effect of an indiscreet zeal. A great number of persons of all ages and sexes made processions, walking two by two with their shoulders bare, which they whipped till the blood ran down, in order to obtain mercy from God, and appease his indignation against the wickedness of the age. They were then called *the devout*; and having established a superior, he was called *the general of the devotion*. Though the primitive Flagellantes were exemplary in point of morals, yet they were joined by a turbulent rabble infected with the most ridiculous and impious opinions, and both the emperors and pontiffs felt themselves called upon to put an end to this religious frenzy, by declaring all devout whipping contrary to the divine law, and prejudicial to the eternal rest of the soul.

This sect was revived in Germany towards the middle of the next century, and, rambling through many provinces, occasioned great disturbances. They held, amongst other absurdities, that flagellation was of equal virtue with baptism and the sacraments; that by means of it the forgiveness of all sins was to be obtained from God without the merits of Jesus Christ; and that the old law of Christ was soon to be abolished, and a new law enjoining the baptism of blood, to be administered by whipping, was to be substituted in its stead. By an injudicious as well as unrighteous policy, Clement VII. thundered out anathemas against the Flagellantes, who were consequently burnt by the inquisitors in several places; but they were not to be easily extirpated. They appeared again in Thuringia and Lower Saxony in the fifteenth century; and rejecting not only the sacraments, but every branch of external worship, placed their only hopes of salvation in faith and flagellation, to which they added other strange doctrines concerning evil spirits. Their leader Conrad Schmidt and many others were very needlessly committed to the flames by German inquisitors about the year 1414.

FLAGEOLET, or FLAJEOLET, a little flute, made of box or other hard wood, and sometimes of ivory, and having six holes besides that at the bottom, the mouth-piece, and the one behind the neck.

FLAIL, an instrument for thrashing corn, consisting, first, of the hand-staff, or piece held in the thrasher's hand; secondly, of the swiple, or that part which strikes out the corn; thirdly, of the caplins, or strong double leathers, made fast to the tops of the hand-staff and swiple; and, fourthly, of the middle band, being the leather thong or fish skin that ties the caplins together.

FLAIR, in nautical language, to incline or hang over. Seamen say that the work flairs over when a ship is housed in near the water, so that the work hangs over a little too much, and is let out broader aloft than is warranted by the due proportion.

FLAMBEAU, a kind of torch made of several thick wicks, covered with wax, and serving to burn at nights in the streets, as also at funeral processions, illuminations, and such like occasions. Flambeaux differ from links, torches, and tapers, in being made square, sometimes of white wax and sometimes of yellow. They usually consist of four wicks or branches about an inch in thickness and three feet in length, made of a sort of coarse hempen yarn half twisted. They are prepared with the ladle, in much the same way as torches or tapers, by pouring the melted wax on the top of the several suspended wicks, and letting it run down to the bottom; an operation which is repeated till the requisite thickness be obtained. After each wick has thus got its proper cover of wax, they are laid out to dry, then rolled on a table, and four of them joined together by means of a red-hot iron. When united, more wax is poured on, until the flambeau is brought to the size required, which is usually from a pound and a half to three pounds. The last thing is to finish their form or outside, which is done with a kind of polishing instrument of wood, by running it along all the angles formed by the union of the branches.

The flambeaux of the ancients were different from ours, having been made of woods dried in furnaces or otherwise. Various kinds of wood were used for this purpose, but that most commonly employed was pine. Pliny says, that in his time oak, elm, and hazel were also frequently used. In the seventh book of the Æneid mention is made of a flambeau of pine; and Servius remarks that flambeaux were also made of the cornel-tree.

FLAMBOROUGH HEAD, a cape or promontory on the eastern coast of Yorkshire, five miles east of Burlington, and 215 from London. This was the *Fleamburg* of the Saxons, having, it is supposed, been so called from the lights made on it to direct the landing of Ina, who, in 547, joined his countrymen in these parts with a large reinforcement from Germany, and founded the kingdom of Northumberland. In the time of Edward the Confessor, Flamborough was one of the manors of Harold, earl of the West Saxons, afterwards king of England; but on his death the conqueror gave it to Hugh Lupus, who bestowed it on the monastery of Whitby. The town is situated on the north side, and consists of about 150 small houses, entirely inhabited by fishermen, few of whom, as is said, die in their beds, but meet their fate in the element with which they are so conversant. The cliffs of the Head are of a tremendous height and amazing grandeur. Beneath are several vast caverns; some closed at the end, others pervious, and all formed with a natural arch. In some places the rocks are insulated, and of a pyramidal figure, soaring up to a vast height. The bases of most are solid, but in some instances they are pierced through and arched. The colour of all these rocks is white, from the dung of the innumerable flocks of migratory birds, which quite cover the face of them. Long. 20. E. Lat. 54. 15. N.

FLAME is a general name for every kind of luminous vapour, provided the light it emits has any considerable degree of intensity. Flame, however, is most generally applied to such as are of a conical figure, like those arising from our common fires; the others are commonly called *luminous vapours*, or *simple lights*. See HEAT.

Flames are of different colours, according to the substances from which they are produced. Thus, the flame of sulphur and spirit of wine is blue; the flame of nitre and zinc, of a bright white; that of copper, of a greenish blue, and so on. These varieties afford an opportunity of making a number of agreeable representations in fireworks, which could not be accomplished if the flame produced from every different substance was of the same colour. See PYROTECHNICS.

FLAMEN, in Roman antiquity, the name of an order of priests, instituted either by Romulus or Numa, authors not being agreed which of the two was its founder.

They were originally only three; the *Flamen Dialis*, *Flamen Martialis*, and *Flamen Quirinalis*. The *Flamen Dialis* was sacred to Jupiter, and a person of the highest consequence and authority in the state. He discharged several religious duties which properly belonged to the kings, and was honoured with many eminent privileges, but was obliged to observe several superstitious restraints. The *Flamen Martialis* was sacred to Mars, and was ordained to inspect the rites of that warlike god. The *Flamen Quirinalis* was sacred to and superintended the rites of Romulus Quirinus. But the Flamines last mentioned, though of high authority, were much inferior to the *Flamen Dialis*; and all three were chosen by the people, and consecrated by the *Pontifex Maximus*. In latter times several priests of the same order and name were added to their number, but inferior in power. The whole at last amounted to fifteen, the first three of whom were senators, and called *Flamines Majores*; whilst the other twelve, taken from among the people, were denominated *Flamines Minores*. According to some authors, the Romans had a Flamen for every deity they worshipped. The greater Flamines wore the robe edged with purple, like the great magistrates, and had an ivory chair, with a seat in the senate. They also had a little band of thread about their heads, and hence their name, *quasi Filamines*, is said to have been derived. The wife of the *Flamen Dialis* was called *Flaminica*, and wore a flame-coloured habit, on which was painted a thunderbolt, whilst above her head-dress she had green oak boughs, to indicate that she belonged to Jupiter the thunderer, to whom the oak was sacred. The Flamines wore each of them a hat or cap called *Flammeum* or *Apex*.

FLAMINIA VIA, an ancient Roman road, constructed by C. Flaminius, during his censorship, 220 B. C. Proceeding from Rome through Etruria in a direct line to Narnia, now *Narni*, in Umbria, it was divided into two branches, the one to the east leading through *Terni* and *Spoleto* to *Foligno*, where it met the other, which passed through *Careoli* and *Bevagna*. It then continued its course to Nuceria, where it again branched off in two directions, the one passing through the district of *Picenum* to Ancona, and along the coast of the Adriatic to *Fanum Fortunæ*, *Fano*, where it met the other, which followed the more direct line of *Intercisa* or *Furlo*, and *Forum Sempronii* or *Fossombrone*. It did not go beyond *Ariminum*. (Bergier, *Hist. des Grands Chemins.*)

FLAMINIUS, C., a Roman senator, one of the most distinguished men of his family, the chief transactions of whose life are comprehended between his tribuneship, 232, and death, 217, B. C. He was one of the most powerful supporters of the liberal party in Rome, and was amongst the first to suggest the idea of dividing the land taken from the *Galli Senones*, in *Picenum*, amongst the lower orders; a suggestion which proved ever afterwards a source of irritation between the aristocracy and plebeians. This proposal made him, of course, the favourite of the people, and detested by the senate, who lost no opportunity of mortifying and thwarting the plans of Flaminius as far as they could do so with safety to themselves. By his influence with the people he was raised to the consulship (223 B. C.), and proceeded with his colleague Furius to conduct the war against the *Galli Insubres*, a powerful tribe in Cisalpine Gaul, to the north of the Po, whose capital was Milan. They had scarcely arrived, when the senate, who had it always in their power to punish a magistrate whose conduct they disapproved, by pretended flaws in the election, or by sacrifices not duly performed, sent an order for their immediate return. The friends of Flaminius had advertised him of the contents of the dispatch, and he, resolving not to be baffled in his object, deposited it quietly in his portfolio, under pretence that he was too much occupied with his military manœuvres to have time to attend to the civil affairs of Rome. But when he had struck a decisive blow against the enemy, and thus justified the support given by his friends at Rome, he opened the dispatch, and found that it contained his recal. He felt himself, however, too powerful in the affections of the people to care for the spleen of the senate, and boldly set it at defiance, by remaining in the north of Italy till he had made a satisfactory arrangement of this part of the country. On his return he was degraded by the senate, but the people indemnified their favourite by voting him a triumph.

Flaminius continued to support every measure calculated to increase the power of the people, or to diminish that of their opponents. He procured the enactment of a law, that no senator should possess a ship of larger burden than was sufficient to contain three hundred amphoræ, equal to about 900 English bushels. This increased still more his influence with the people, and he was again elected consul (217 B. C.), though absent at *Ariminum*, to which place he had retired to await the result of the election. He was fearful that the senate would manage to retain him in the city, by falsifying the auspices or delaying the celebration of the *Feriæ Latinæ*. They attempted to recal him, but he disregarded their commands, and took his station at *Arretium*, now *Arrezzo*, to wait the arrival of Hannibal. But that artful general drew the army of Flaminius into the ambuscade he had laid on the Thrasymene Lake, and the result was the complete defeat of the army and death of Flaminius. (Polyb. ii. 21, 32, 33; Cic. *Acad.* iv. 5; Liv. xxi. xxii.)

Flaminius, *T. Quinctius*, an illustrious Roman senator, born about 228 B. C., at a time when his country was engaged in important wars, which drew forth all the talent it possessed. His early youth was passed in arms against Hannibal; and so much did he distinguish himself in the various duties he was called on to discharge, that he ventured to stand candidate for the consulate before the legal age, and without having passed through the inferior offices. His canvass was successful, and he became consul at the age of thirty (198 B. C.). The Romans had for several years been engaged in a contest with Philip III. king of Macedon, whose supremacy extended over the whole of Greece; and he had as yet baffled all attempts made by them to bring him under subjection. The war with this monarch was entrusted to the young Flaminius; and by the wisdom and vigour of his measures he compelled Philip to retreat from a strong position on the river Apsus in Epirus, where he had hitherto been able to set the Roman generals at defiance. This opened up to him the road to Thessaly, where he had no sooner arrived than the whole country declared itself in his favour. The mildness of his manners, his affability, and constant regard to the strict rules of justice, gained him the hearts of all who approached him; but Philip was determined not to yield the power which he had inherited from his ancestors without a struggle. The armies met at Cynoscephalæ in Thessaly, to the south of the river Peneus, small hills so called from their resemblance to the heads of dogs; and the result was the entire defeat of Philip (197 B. C.). Though that monarch was entirely in his power, Flaminius restored to him his kingdom, but compelled him to renounce all claim to the sovereignty of Greece. He prevailed on the commissioners, who had been sent by the senate to assist him in settling the affairs of Greece, to declare its entire independence, and to withdraw the garrisons from all its cities. The wisdom of this policy was soon effectually proved; as Greece became more completely attached to the Roman dominion from affection than she could ever have been by force. In the latter years of his life we find him employed in a mission to which, from his noble character and humane disposition, we can scarcely give credit. He was sent (183 B. C.) by the senate to demand from Prusias king of Bithynia, that Hannibal should be given up to the Romans; and though Prusias used every intercession in favour of a man who lived with him under the sanction of hospitality, he could not prevail. Flaminius, it seems, insisted that his demand should be granted; and, to escape his enemies, Hannibal put an end to his life by poison. Plutarch states that there is some doubt whether Flaminius was employed in this embassy; and we would fain believe that he did not tarnish his character by conduct so utterly unworthy of it. (Plutarch, *Life of Flaminius*; Livy, xxxii. xxxiii. xxxiv.)

FLAMSTED, a village and parish of England, in the county of Hertford, anciently called Verlamstedt, from its vicinity to the river. The population amounted in 1831 to 1462.

FLAMSTEED, John, an eminent English astronomer, and the first who obtained the appointment of astronomer-royal, was born at Derby in the year 1646. He was educated at the free school of Derby, where he was head scholar at fourteen years of age, at which period his constitution, naturally delicate, sustained a severe trial by an attack of illness. When some of his companions went to the university, the state of his health prevented him from accompanying them. He afterwards met with a treatise *De Sphæra*, by Sacrobosco, a work which, being perfectly suited to the natural turn of his genius, he perused with uncommon satisfaction, translating as much of it into English as he thought could be necessary for him; and from the *Astronomia Carolinæ* of Street he learned the method of calculating eclipses, and ascertaining the places of the planets. Mr Hatton, a mathematician, sent him Kepler's *Tabulæ Rudolphinæ*, and Riccioli's *Almagestum Novum*, together with some other astronomical works to which he was as yet a stranger. In 1669 he calculated an eclipse of the sun, which had been omitted in the Ephemerides, together with five appulses of the moon to fixed stars, and sent them to Lord Brouncker, then president of the Royal Society, who submitted them to the examination of that learned body, by whom they were greatly applauded, and Flamsteed received letters of thanks from Mr Oldenburg the secretary, and from Mr John Collins, one of the members. In 1670, being invited by his father to come up to London, in order that he might become personally acquainted with his learned correspondents, he gladly accepted the invitation, and had an interview with Mr Oldenburg and Mr Collins, by the latter of whom he was introduced to Sir Jonas Moore, who became his warm friend and patron. In consequence of this journey he became acquainted with many astronomical instruments, and was presented with Townley's micrometer by Sir Jonas Moore, who also assisted him in procuring glasses at a moderate rate for the construction of telescopes. On his way home he paid a visit to Dr Barrow and Mr, afterwards Sir Isaac Newton, at Cambridge, and entered himself as a student of Jesus College.

In the year 1672, he made large extracts from the letters of Gascoigne and Crabtree, by which his knowledge of dioptrics was much improved; and during the same year he made a number of celestial observations when the weather would permit, which were afterwards published in the *Philosophical Transactions*. In 1673 he composed a treatise on the true and apparent diameters of the planets, when at their greatest and least distances from the earth; a work from which even Newton himself did not scruple to borrow, and of which he made some use in his *Principia* in 1685. In 1674, Flamsteed published an Ephemeris, in which he exposed the folly and absurdity of astrology; and the same year he drew up a table of the tides for the use of the king, with an astronomical account of their ebbing and flowing, which Sir Jonas Moore assured him would be well received by his majesty. Sir Jonas received from Mr Flamsteed a pair of barometers, with directions how to use them, which he presented to the king and the duke of York, to whose notice he embraced every opportunity of introducing Mr Flamsteed.

Having taken the degree of master of arts at Cambridge, he formed the resolution of entering into holy orders, when Sir Jonas wrote to him to come to London, where he had an appointment for him very different from any in the church. But as Sir Jonas found that nothing could induce him to abandon the resolution he had formed, he obtained for him a situation which was perfectly consistent with the character of a clergyman. This was the new office of astronomer to the king, with a salary of L.100 per annum. In Easter 1675, he received ordination at Ely-House by Bishop Gunning; and on the 10th of August the same year was laid the foundation stone of the royal observatory at Greenwich, which received the designation of Flamsteed-House, in honour of the first astronomer-royal. Till this edifice was erected, he made his observations in the queen's house at Greenwich; and in 1681 Flamsteed's *Doctrine of the Sphere* was published by Sir Jonas Moore in his *System of the Mathematics*. But notwithstanding his extraordinary merit, he never rose higher in the church than the living of Burslow in Surrey, although he was held in deserved estimation by the greatest men in the nation. He corresponded with Sir Isaac Newton, Dr Halley, Mr Molyneux, Dr Wallis, and many others; whilst M. Cassini and he commenced their respective discoveries with the utmost confidence and cordiality. But none of his works contributed so much to establish his fame as his *Historia Cœlestis Britannica*, in three volumes folio. Mr Flamsteed was suddenly carried off by a stranguary, on the 31st of December 1719, having, notwithstanding the extreme delicacy of his constitution, and incessant labour, reached the seventy-third year of his age.

FLANDERS, a province of the Netherlands, bounded by the German Ocean and the United Provinces on the north, by the province of Brabant on the east, by Hainault and Artois on the south, and by another part of Artois and the German Sea on the west; being about sixty miles long and fifty broad. See Netherlands.

FLANEL, or Flannel, a kind of slight, loose, woollen stuff, composed of a woof and warp, and woven on a loom with two treddles, after the manner of baize.

Dr Black assigns as a reason why flannel and other substances of the same kind keep the body warm, that they compose a rare and spongy mass, the fibres of which touch each other so lightly, that the heat moves slowly through the interstices, which being filled only with air, and that too in a stagnant state, give little assistance in conducting the heat. From the experiments of Count Rumford, it appears that there is no relation between the power which the substances usually worn as clothing have of absorbing moisture, and that of keeping the body warm. Having provided a quantity of each of these substances mentioned below, he exposed them, spread out upon clean china plates, for the space of twenty-four hours, to the warm and dry air of a room which had been heated by a German stove for several months, and during the preceding six hours had raised the thermometer to 85° of Fahrenheit; after which he weighed equal quantities of the different substances with a very accurate balance. They were then spread out upon a china plate, and removed into a very large uninhabited room upon the second floor, where they were exposed forty-eight hours upon a table placed in the middle of the room, the air of which was at 45° of Fahrenheit. At the end of this time they were weighed, and then removed into a damp cellar, where they were placed on a table in the middle of the vault, the air of which was at the temperature of 45°, and, by the hygrometer, seemed to be fully saturated with moisture. In this situation they were suffered to remain three days and three nights, the vault being all the while hung round with wet linen cloths, to render the air as completely damp as possible. At the end of three days they were weighed, and the weights at the different times were found as in the following table:—

		Weight after being dried in the hot room.	Weight after coming out of the cold room.	Weight after remaining 72 hours in the vault.
Sheep's wool		Parts 1000	1084	1163
Beaver's fur			1072	1125
The fur of a Russian hare			1065	1115
Eider down			1067	1112
Silk	Raw single thread		1057	1107
	Ravellings of white taffety		1054	1103
Linen	Fine lint		1046	1102
	Ravellings of fine linen		1044	1082
Cotton wool			1043	1089
Ravellings of silver lace			1000	1000

In regard to these experiments our author observes, that though linen, from the apparent ease with which it receives dampness from the atmosphere, seems to have a much greater attraction for water than any other, yet it would appear, from what is related above, that those bodies which receive water in its unelastic form with the greatest ease, or are most easily wet, are not those which in all cases attract the humidity of the atmosphere with the greatest avidity. "Perhaps," says he, "the apparent dampness of linen to the touch arises more from the ease with which that substance parts with the water it contains, than from the quantity of water it actually holds; in the same manner as a body appears hot to the touch, in consequence of its parting freely with its heat; while another body which is really at the same temperature, but which withholds its heat with great obstinacy, affects the sense of feeling much less violently. It is well known that woollen clothes, such as flannels, &c. worn next the skin, greatly promote insensible perspiration. May not this arise principally from the strong attraction which subsists between wool and the watery vapour which is continually issuing from the human body? That it does not depend entirely on the warmth of that covering, is clear; for the same degree of warmth produced by wearing more clothing of a different kind, does not produce the same effect. The perspiration of the human body being absorbed by a covering of flannel, it is immediately distributed through the whole thickness of that substance, and by that means exposed, by a very large surface, to be carried off by the atmosphere; and the loss of this watery vapour which the flannel sustains on the one side by evaporation, being immediately restored from the other, in consequence of the strong attraction between the flannel and this vapour, the pores of the skin are disencumbered, and they are continually surrounded by a dry and salubrious atmosphere."

Our author expresses his surprise that the custom of wearing flannel next the skin should not have prevailed more universally. He is confident it would prevent a number of diseases; and he thinks there is no greater luxury than the comfortable sensation which arises from wearing it, especially after one is a little accustomed to it. "It is a mistaken notion," says he, "that it is too warm a clothing for summer. I have worn it in the hottest climates, and at all seasons of the year, and never found the least inconvenience from it. It is the warm bath of perspiration confined by a linen shirt wet with sweat, which renders the summer heats of southern climates so unsupportable; but flannel promotes perspiration, and favours its evaporation; and evaporation, as is well known, produces positive cold.

It has been observed that new flannel, after some time wearing, acquires the property of shining in the dark, but loses it on being washed. (*Philosophical Transactions*, No. 483, sect. 7.)

FLANK, or Flanc, in the manège, is applied to the sides of a horse's buttock. In a strict sense, the flanks of a horse are the extremes of the belly, where the ribs are wanting, and are immediately below the loins.

Flank, in *War*, is used by way of analogy for the side of a battalion, brigade, division, or army, in contradistinction to the *front* and *rear*.

Flank, in *Fortification*, is a line drawn from the extremity of the face towards the inside of the work. Or, flank is that part of a bastion which reaches from the curtain to the face, and defends the opposite face, the flank, and the curtain.

Fichant Flank is that whence a cannon playing fires directly on the face of the opposite bastion.

Rasant or *Razant Flank* is the point whence the line of defence begins, from the conjunction of which with the curtain the shot only rases the face of the next bastion; and this happens when the face cannot be discovered but from the flank alone.

FLANNAN Islands, a group of small islands, some six or seven in number, lying twelve miles north-west of the Isle of Skye. They are wild, rocky, and uninhabited; but from the remains of sacred edifices found upon them, they must formerly have been the residence of some Culdean or other religious order. At present they are noted for sheep pasturage.

FLATS, in *Music*. See Interval.

FLAT Island, a small island in the Eastern Seas, situated near the north coast of the island of Flores. Long. 120. 59. E. Lat. 7. 59. S. Also an island in the Mergui Archipelago, lat. 10. 27. N.; and another near the east coast of New Zealand, long. 183. 13. W. lat. 37. 40. S.

FLAVEL, John, an eminent non-conformist minister, was educated at University College, Oxford. He became minister, first of Deptford, and afterwards of Dartmouth, in Devonshire, where he resided the greater part of his life, much respected and admired for his preaching, although he was persecuted on account of his principles in 1685, when several of the aldermen of the town, attended by the rabble, carried about an effigy of him, to which were affixed the bill of exclusion and the covenant. Upon this occasion he thought it prudent to withdraw from the town, not knowing what treatment he might experience at the hands of a riotous mob, headed by magistrates who were themselves amongst the lowest of mankind. Part of his Diary, printed with his remains, will give the reader a high idea of his piety. He died in 1691, at the age of sixty-one; and after his death, his works, which consisted of many pieces of practical divinity, were printed in two volumes folio. Amongst these the most curious are his *Navigation Spiritualized, or a New Compass for Seamen*, of which there have been several editions in 8vo; and *Husbandry Spiritualized*, with occasional meditations upon beasts, birds, trees, flowers, rivers, and several other objects, of which also there have been many editions in 8vo.

FLAX. For some particulars as to the culture of flax, see the article Agriculture. What more remains to be said will be found under the connected head of Hemp.

FLAXMAN, John, an eminent English sculptor, was born at York on the 6th of July 1755. He was the second son of John Flaxman, a moulder in plaster, who, besides keeping a shop in London for the sale of his figures, sought employment in the country. He was of a weakly constitution, and slightly deformed, which prevented him from mingling with associates of his own age in the robust pastimes of youth. But he was not idle. Behind his father's counter he usually seated himself during the day, and, with drawing materials before him, busily employed himself in transferring to paper representations of the numerous figures with which he was surrounded. Indeed, almost from childhood he evinced that partiality for and love of works of art, in the creation of which he so much excelled in maturer years. But he did not confine himself to copying alone. Young as he was, he had dipped into the Iliad, and actually attempted to design historical illustrations of that immortal epic. His education seems to have devolved principally upon his parents; and as his thirst for knowledge was great, the superintendence of his studies must have been an easy task. At his books and models he laboured incessantly, and before he entered his tenth year he had made a great number of small models in plaster of Paris, wax, and clay, some of which are still preserved; and, besides being interesting as the first efforts of genius, they possess considerable merit as works of art. At ten years of age, a salutary change took place in his health. He became strong, lively, and active; and the crutches, by means of which he had hitherto walked, were thrown aside, not to be again resumed. With renovated health he came to the determination to follow sculpture as a profession. In his father's shop, where he assiduously pursued his studies, he learned form and proportion from the casts of antique statues which it contained; whilst in the woods and fields, to which he could now repair, he was supplied with new images and ideas of beauty. At the house of a Mrs Mathew, whose husband had been attracted to the youthful sculptor, Flaxman often spent his evenings hearing her read Homer and Virgil, and discourse upon sculpture and poetry; for the lady was very accomplished, and the companion of Mrs Montague, Mrs Chapone, and Mrs Barbauld. Here he was encouraged to acquire the dead languages, so necessary to one of his profession; and although he never attained to great scholarship, he, by this desultory mode of study, obtained such a knowledge of Greek as enabled him to embody the ideas of the ancient poets in a manner which no modern artist has surpassed. He embodied those passages which caught his fancy whilst he sat listening to Mrs Mathew; and the taste which he displayed in these juvenile efforts induced a gentleman to order six large drawings in chalk, the subjects being chosen from antiquity. The praise which was bestowed upon them gave new impulse to the genius of the youth, and refreshed that consciousness of superior power which he early experienced. But he never overrated himself, nor allowed his industry to relax on account of the flatteries of friends. He continued to labour assiduously in his vocation, well knowing that it was only in this manner that he could attain great eminence, and succeed in embodying those idealised conceptions of beauty which, although they scarcely admit of being defined or described, are nevertheless not less real, nor less universally acknowledged.

In his fifteenth year Flaxman became a student of the Royal Academy, and soon made himself known by assiduous and enthusiastic application. In the same year he carried off the silver medal; and in due time became a candidate for the gold one, the reward of the highest degree of merit, but proved unsuccessful. This defeat, however, only increased his assiduity. But finding himself now compelled to labour for bread, he was employed by the Wedgewoods, the enterprising potters, in making designs for adorning their wares. His sketches consisted chiefly of small groups in very low relief, the subjects being taken from ancient poetry and history. Previously to this period the porcelain of England had little external beauty to recommend it; and the genius of Flaxman may be said to have created this branch of art in his native country. The rude and unseemly shapes which formerly prevailed were no longer tolerated, and figures of classic elegance and beauty were invented to supply their place. In 1782, Flaxman having quitted his paternal roof, took a small house, and entered into a matrimonial alliance with a person of considerable accomplishments, in whose society he enjoyed much domestic happiness. During the ten years which preceded this event, he had exhibited some thirteen works at the Royal Academy, but, from the pecuniary difficulties under which he laboured, none of these were executed in marble. Shortly after his marriage, he formed the resolution of studying at Rome, and at the end of five years of incessant labour, during which he executed several monuments and other works of considerable merit, he was enabled to carry his design into execution. It is unnecessary to observe, that Flaxman, like every other artist, was struck with the noble specimens of art which Italy possesses, and that by a close study of these he greatly improved himself. But he was no servile imitator, for he was as capable of creating as of copying. In Rome Flaxman executed a number of works. For three individuals of his own country he illustrated Homer, Æschylus, and Dante. These designs are splendid, being varied with great skill, and drawn with a fine sense of the beautiful and harmonious in composition. Of works in marble he executed a small size group of Cephalus and Aurora; a statue of Lord Mansfield; a group representing the fury of Athamas, from Ovid's *Metamorphoses*, consisting of four figures of the heroic size; and the restoration of that splendid torso which is generally believed to be a fragment of a Hercules. This last undertaking was as difficult as it turned out to be thankless. He not only completed the figure of Hercules, but added another of Omphale. But this statue did not give satisfaction to the connoisseurs of Italy, and Flaxman caused it to be destroyed some time previously to his death, without any injury to his fame. The remains of ancient sculpture in Rome, and in other cities of Italy, engaged not a little of his attention. He executed numerous drawings, and made a great many memoranda, the most valuable of which were subsequently embodied in his lectures on sculpture. He had been elected a member of the academies of Florence and Carrara; and after seven years' residence in a foreign country, he at length returned to his own.

Flaxman's statue of Lord Mansfield had raised the expectations of his countrymen to a high pitch. In 1797 he was elected associate of the Royal Academy, during which year he sent to the exhibition three sketches in bas-relief from the New Testament, and a monument to Sir William Jones. The sketches are distinguished for their elegance of grouping. The monument is a bas-relief, but not one of the artist's most fortunate efforts in that line. In the forty-fifth year of his age Flaxman was elected a member of the Royal Academy, and, as is usual on such occasions, presented to the institution a work of art. His offering on this occasion was a marble group of Apollo and Marpessa; the conception of which is fine, though the workmanship is not so good. In the mechanical use of the chisel he never excelled. It was now his ambition to be employed upon some great national work, and he proposed to make a statue of Britannia two hundred feet in height, but the project was not carried into execution. His fame, however, was now firmly established, and employment flowed rapidly in. A quick succession of noble works followed from his hand, one of which, a monument in memory of the family of Sir Francis Baring, is considered among the greatest efforts of the national genius of England. One of his biographers remarks with respect to it, "This is one of the finest pieces of motionless poetry in the land." Of historical monuments Flaxman executed several, but they are not equal to his other works. They have been admired for the fine sentiment which pervades them, but their execution is considered by many as too coarse and heavy. The statue of Sir Joshua Reynolds is one of his best productions. But the works he loved most were those which embodied poetical passages in the Bible, and of these he executed a great number. In 1810 the Royal Academy created a professorship of sculpture, and bestowed it upon Flaxman. His lectures are ten in number. The style is rather heavy; yet although his compositions are destitute of those flashes of poetry which irradiate the pages of Fuseli, they display a very comprehensive knowledge of the subject, much sound sense, and are more calculated to convey definite information to the student than those of the other artist above named. But if the offspring of his pen was cold and uninformed with ideal beauty, the productions of his pencil and chisel display an exuberance of imagination. His sketches and drawings are very numerous. Amongst the works which he illustrated were the Pilgrim's Progress, Sotheby's translation of Oberon, and Hesiod. These designs are in all respects fully equal to his other works, and unsurpassed by any thing which ever was executed in that line. During the last ten years of his life Flaxman produced some of his noblest works. Amongst these were the group of the Archangel Michael vanquishing Satan, the Shield of Achilles, Psyche, the Pastoral Apollo, and the statues of Michel Angelo and Raffaelle. The first is a work of the highest merit, and worthy of the great poem which it illustrates. "In the Psyche and the Pastoral Apollo," says Mr Allan Cunningham, "the genius of him who illustrated Homer is sufficiently apparent; a certain austere composure is breathed over them. The Michael Angelo and the Raphael are poetic, yet real; heroic, yet familiar; and their costume, though not antique, is at once historic and picturesque." Flaxman's statues of Burns and Kemble, executed about the same time, are scarcely so happy. Amongst his other works were monuments to Collins at Chichester, and to Earl Howe in St Paul's; and statues of Washington, Nelson, Pitt, and Sir John Moore. They are of various excellence, yet all more or less bear the impress of genius and taste. But the career of this great sculptor was drawing to a close. In the beginning of December 1826 he was seized with an inflammation of the lungs, which terminated fatally on the 7th of the same month.

In stature Flaxman was small, and his figure was slim. In manners he was mild, gentle, and placable; and his mind, whilst it was rich in the gifts of genius, was embued with unaffected piety. Of his works there are four kinds; the religious, the poetic, the classic, and the historical. In each of these he has left specimens which entitle him to rank very high as an artist, but in all he has not attained the same degree of excellence. In the historical and the classic he was less successful; but in the religious and poetic he has been surpassed in purity, simplicity, and taste, by no modern sculptor. His religious compositions consist of groups and figures embodying moral and spiritual passages from Scripture. They are generally of small dimensions, but very numerous. His mind was essentially poetical; and his productions are embued with the finest inspiration. It was probably of some of these works that Sir Thomas Lawrence spoke when he said of Flaxman, "His solitude was made enjoyment to him by a fancy teeming with images of tenderness, purity, or grandeur. His genius, in the strictest sense of the words, was original and inventive." His lectures were published in 1829, in one vol. 8vo, illustrated with fifty-two plates.

FLEAM, in *Surgery* and *Farriery*, an instrument for letting blood of a man or horse. A case of fleams, as it is called by farriers, comprehends six sorts of instruments; two hooked ones, called *drawers*, which are used for cleansing wounds; a pen-knife; a sharp-pointed lancet for making incisions; and two fleams, one sharp and the other broad pointed. These last are somewhat like the point of a lancet, fixed in a flat handle, and no longer than is just necessary to open the vein.

FLECHE, LA, an arrondissement in the department of the Sarthe, in France. It extends over 722 square miles, is divided into seven cantons, and these into eighty communes, containing 84,995 inhabitants. The capital, a city of the same name, is a well-built place, situated on the river Loir, in a valley surrounded with vineyards. It contains 843 houses, and 5099 inhabitants. There is a public school for military instruction, with a good library. Long. 0. 13. W. Lat. 47. 22. N.

FLECHIER, ESPRIT, bishop of Nismes, one of the most celebrated preachers of his age, and author of a number of works, was born at Pernes, a small town in the diocese of Carpentras, on the 10th of June 1632, and educated under the eye of his uncle, Father Audifret, general of the congregation of Christian doctrine, a learned and estimable man. According to the constitution of the congregation, Fléchier, having completed his own education, was immediately employed in teaching. In 1659, when only twenty-seven, he professed rhetoric at Narbonne, and there pronounced the funeral oration of M. de Rebé, archbishop of that city, which, however, is not to be found in his collected works, probably because it was deemed unworthy of the reputation which he subsequently acquired. A few months afterwards, on the death of Audifret, followed as it was by some changes in the government of the congregation, which he did not relish, Fléchier laid aside the habit of the *doctrinaires*, and proceeded to Paris, where he was at first employed in the humble occupation of a parochial catechist; but he soon made himself known by his Latin and French poetry, and particularly by a description in Latin verse of the brilliant carousal, *Circus Regius*, given by Louis XIV. in 1602. This was the commencement of Fléchier's reputation. He was now entrusted with the education of Louis Urbain Lefèvre de Caumartin, afterwards intendant of finances and counsellor of state; and as the house of Louis de Caumartin, the father of his pupil, was then frequented by the most considerable personages both of the court and the city, Fléchier was thus introduced into the first society, amongst which his talents, amiability, gentleness of demeanour, and regularity of manners, soon procured him many friends. The Duke of Montausier, who was not prodigal of his notice, conceived a great regard for Fléchier, declared himself his patron, and having presented him to the dauphin, procured him the place of reader to that young prince. The sermons of Fléchier increased his reputation, which was afterwards raised to the highest pitch by his funeral orations. Having been chosen to pronounce that of Madame de Montausier, he displayed so great talent on the occasion that his discourse opened to him the doors of the French Academy, into which he was received in 1673, in the room of M. Godeau, bishop of Venice. He was admitted the same day with Racine, and having precedence in addressing the Academy, his discourse was warmly applauded; the great poet however was less fortunate than the orator, for his address being scarcely audible, was coldly received and unfavourably judged of; so much is chance concerned even in the success of eminent merit. The favours of the court now flowed upon Fléchier. The king gave him successively the abbey of St Leverin, in the diocese of Poitiers, the office of almoner to the dauphiness, and, in 1685, the bishopric of Lavaur, accompanying his kindness with the most flattering expressions of favour and regard. "I have made you wait a little for a place which you have long merited," said the monarch; "but I did not wish to deprive myself sooner of the pleasure of hearing you." From the see of Lavaur Fléchier was, in 1687, translated to that of Nismes, which was more valuable, and also accounted more honourable. His own wish was to remain at Lavaur; but the king overcame his repugnance to the proposed translation by making him sensible that he would be more useful to the church at Nismes than at Lavaur, and that in the former place there was more labour to be performed and more good to be done. In fact the Calvinists were very numerous at Nismes; and although several had made abjuration, their conversion was at best but equivocal. But Fléchier, by his prudent conduct, in which zeal was tempered by charity, brought back the greater number of these sectaries to the bosom of the church, and made himself esteemed and beloved even by those who declined to abjure their faith. During the troubles in the Cevennes he softened, as much as in him lay, the rigour of the edicts, and showed himself so sensible of the evils of persecution, and so indulgent even to what he regarded as error, that his memory is, even at this day, held in veneration amongst the Protestants of that district. In the famine which succeeded the winter of 1709, he distributed immense sums, making no distinction between Catholics and Protestants; all were his children, and all shared his beneficence in proportion to their respective wants. He also published an eloquent pastoral letter on the subject of a cross of St Gervais, which, it was pretended, worked miracles, and warned his flock against those lying wonders, by which the credulity of the people has frequently been abused. This appears to have been amongst his last efforts in the cause of truth and religion. The good bishop, indeed, foresaw that his end was now approaching; and, having prepared for himself a humble tomb, he died at

Montpellier on the 16th February 1710, at the advanced age of seventy-eight. "He died," says D'Alembert, "lamented by the Catholics, regretted by the Protestants, and having always exhibited to his brethren an admirable model of zeal and charity, simplicity and eloquence." Fléchier's works are, 1. *Antonii Mariæ Gratiani de Vita Joannis Francisci Commendoni Cardinalis* libri iv. Paris, 1669, in 12mo; 2. *La Vie du Cardinal Commendon*, Paris, 1671, in 4to; 3. *De Casibus Virorum Illustrium autore Antonio Maria Gratiano, opera et studio Sp. Flecherii*, Paris, 1680, in 4to; 4. *Histoire de Théodose-le-Grand*, Paris, 1679, in 4to, composed for the education of the dauphin; 5. *Histoire du Cardinal Ximenes*, Paris, 1693, in 4to; 6. *Oraisons Funèbres*, 1681, in 4to and in 12mo; 7. *Panégyriques des Saints*, Paris, 1690, in 4to; 8. *Sermons de Morale prêchés devant le Roi, avec des Discours synodaux et les Sermons prêchés par Fléchier aux Etats de Languedoc et dans sa Cathédrale*, in 3 vols. 12mo; 9. *Œuvres Posthumes, contenant ses Harangues, Compliments, Discours, Poésies Latines, Poésies Françaises*, Paris, 1712, in 12mo; 10. *Mandements et Lettres pastorales, avec son Oraison funèbre par l'Abbe du Jarry*, Paris, 1712, in 12mo; 11. *Lettres Choisies sur divers sujets*, Paris, 1715, in 2 vols. 12mo; 12. *Relation d'un Voyage en Auvergne.* The only collection yet published of the works of Fléchier is that of the Abbé Ducreux, canon of Auxerre, which appeared under the title of *Œuvres Complètes de Messire Esprit Fléchier*, Nismes, 1782, in 10 vols. 8vo. If we except the History of Theodosius, pulpit eloquence is the only branch of the belles-lettres cultivated by Fléchier in which he excelled. His Funeral Orations have been compared with those of Bossuet, without attending to this distinction, that comparisons become useless between two kinds of genius which are totally different. That of Bossuet was sublime throughout. Fléchier, on the other hand, was only remarkable for the nobleness of his thoughts and the harmony of his diction. It is true that he possessed in an eminent degree these two qualities of an orator, and that nobody has carried the latter further than he; but even in that department where he has been most successful, Fléchier is not without faults, and may be reproached with an ambition of giving point to his thoughts, an affectation of symmetry in the style, and a love of antitheses, all at variance with the principles of good taste. But if his funeral orations and sermons lose much of their merit by a too measured elegance, his pastoral instructions and synodal discourses are wholly free from such affectation, indeed as remarkable for simplicity of style as for generosity of sentiment, and that indulgent spirit which laments whilst it combats error, and which, repudiating all attempts at persecution, seeks to win men over to the right way, not by the instrumentality of fear, but through the medium of their understanding and affections. "C'est dans ces ouvrages," says a distinguished French critic, "que la philosophie elle-même apprendra l'usage qu'on doit faire des lumières et du sentiment, et se convaincra que l'humanité n'a pas de consolation plus solide que la religion, comme la politique n'a pas de meilleur appui." (A.)

FLECKNOE, Richard, an English poet and dramatic writer in the reign of Charles II. who has been more indebted for the preservation of his name to Dryden's satire of *Mac-Flecknoe*, than to the merit of his own productions, is said to have been originally a Jesuit, and connected with some persons of distinction belonging to the Roman Catholic persuasion. The origin of Dryden's antipathy to this man has not been ascertained. It was confirmed, however, when the office of poet-laureat, of which Dryden had been deprived on account of his religion, was conferred upon Flecknoe; and resentment of this wrong appears to have produced the celebrated satire above mentioned, which, besides being equally spirited and amusing in itself, served in some degree as the model of the Dunciad. Flecknoe wrote some plays, but not more than one of them was ever acted. His comedy called *Damoiselles à la Mode* was printed in 1667, and addressed to the Duke and Duchess of Newcastle; but the players refused to perform it. His other dramatic pieces were *Ermina, or the Chaste Lady; Love's Dominion*, printed in 1654; and *The Marriage of Oceanus and Britannia.* His other works consist of, 1. *Epigrams and Enigmatical Characters*, 1670, in 8vo; 2. *Miscellanea*, or Poems of *all* sorts, with divers *other* pieces, 1653, in 12mo; 3. *Diarium*, or the Journal, divided into twelve Jornadas, in burlesque verse, London, 1656, in 12mo. Flecknoe died in 1678. Mr Southey, in his *Omniana*, has generally endeavoured to vindicate him from some of the ridicule thrown upon him as a writer, and from certain grave reproaches made against his character as a man. (A.)

FLEECE, the covering of wool shorn off the bodies of sheep. See the article Wool.

FLEET commonly implies a company of ships of war belonging to any prince or state; but sometimes it denotes any number of trading ships employed in a particular branch of commerce.

Fleet is also a noted prison in London, where persons are committed for contempt of the king and his laws, particularly of his courts of justice; or for debt, where any person will not or cannot pay his creditors. See London.

FLEETWOOD, William, a learned English bishop, descended of an ancient family in Lancashire, was born in the Tower of London, where his father resided, on the 21st of January 1656. He received his education at Eton, and at King's College, Cambridge. About the time of the Revolution he entered into holy orders, and having soon become a distinguished preacher, was appointed chaplain to King William and Queen Mary. By the interest of Dr Godolphin, vice-provost of Eton, and residentiary of St Paul's, he was appointed rector of St Austin's, London, which is in the gift of the dean and chapter of St Paul's; and soon afterwards he also obtained the lectureship of St Dunstan's in the West. In 1691 he published his *Inscriptionum Antiquarum Sylloge*, in two parts; one containing remarkable Pagan inscriptions, and the other ancient Christian monuments. In 1692 he published a translation of Jurieu's *Plain Method of Christian Devotion*, the twenty-seventh edition of which was printed in 1750. In 1701 appeared his Essay on Miracles, which called forth the animadversions of several writers, particularly Hoadly. In 1704 he published anonymously, The Reasonable Communicant; and in 1705, Sixteen Practical Discourses on the relative duties of parents and children, husbands and wives, masters and servants, with three sermons on the case of self-murder. Having a natural inclination for the study of British history and antiquities, he gave a specimen of his skill in these pursuits by publishing, in 1707, his *Chronicon Preciosum*, containing an account of the English money, the price of corn and other commodities, for the preceding six hundred years. In the previous year he had, without any solicitation on his part, been nominated to the see of St Asaph, upon the death of Beveridge; but he was not consecrated until June 1708. His conduct as a bishop was highly exemplary, and such as became the episcopal character. In 1710 he published a vindication of the thirteenth chapter to the Romans, upon the authority of which the regal dignity had been so magnified by some as to make tyranny seem an ordinance of God, and to represent the most abject slavery as founded upon the principles of religion. This degrading doctrine was highly offensive to Bishop Fleetwood, who, in this tract, contends that, in the chapter referred to, St Paul requires of no people any more submission to the higher powers than that which is enjoined by the laws of their several countries.

In 1712 he published Four Sermons, one on the death of Queen Mary in 1694, another on that of the Duke of Gloucester in 1700, a third on that of King William in 1701, and a fourth on the accession of Queen Anne; and also, the same year, an anonymous tract on Lay Baptism, according to the Church of England, a subject which then engaged a good deal of attention. The Life and Miracles of St Wenefrede, together with her Litanies, appeared in 1713, likewise without his name; the object of which was to expose the absurd superstitions by which weak minds are apt to be influenced, and, in particular, to show the delusions which had been practised under the names of pretended saints. In 1714 he was translated from the see of St Asaph to that of Ely, vacant by the death of Dr Moore, and continued there till his death, which took place at Tottenham, Middlesex, on the 4th of August 1723. The remaining works of Bishop Fleetwood are these: 1. The Chancellor's Plea in the Divorce of Sir G. Downing, 1715; 2. Papists not excluded from the Throne on account of Religion, 1717; 3. A Letter from Mr T. Burdett, executed at Tyburn for the murder of Captain Falkner, to some attorneys' clerks of his acquaintance, 1717; 4. A Letter to an Inhabitant of the Parish of St Andrews, Holborn, about New Ceremonies in the Church, 1717; and, 5. A Defence of Praying before Sermon, as directed by the fifty-fifth canon. All these tracts, however, were published without the author's name. Bishop Fleetwood's character stood deservedly high in general estimation. His virtue was without any alloy of fanaticism, and his piety wholly untinctured with superstition. He was the friend of liberty and learning, equally zealous in defending the one and in encouraging the other. He assisted Dr Hickes in his great work, *Linguarum veterum Septentrionalium Thesaurus;* and Hearne confesses himself to have been under many obligations to the same excellent person. In a professional point of view he was unquestionably the best preacher of his time; and his occasional sermons exhibit a felicity of adaptation to the circumstances that had called them forth, which we should perhaps seek for in vain in any other compositions of the kind. In a word, Dr Fleetwood was an honour to the church, of which he was a distinguished member, and an ornament to a hierarchy which has been illustrated by some of the greatest names to be found in the history of English literature. (A.)

FLEMINGIANS, or FLANDRIANS, in *Ecclesiastical History*, a sect of rigid Anabaptists, who acquired this name in the sixteenth century, by way of distinction from the *Waterlandians*. In consequence of some dissensions among the Flemingians relative to the treatment of excommunicated persons, they were divided into two sects, distinguished by the appellations of *Flandrians* and *Frieslanders*, who differed from each other in their manners and discipline. But in process of time many of these came over to the moderate community of the Waterlandians, whilst those who continued separate still retained the name of the old Flemingians or Flandrians. They maintained the opinion of Menno with respect to the incarnation of Christ; alleging that his body was produced by the creative power of the Holy Ghost, and not derived from his mother Mary.

FLEMISH, or the FLEMISH TONGUE, that which is otherwise called *Low Dutch*, to distinguish it from the *German*, of which it is a corruption and a kind of dialect. It differs from the *Walloon*, which is a corruption of the French language. The Flemish is used throughout all the provinces of the Netherlands.

FLENSBURG, a city of the duchy of Sleswick, in Denmark. It is finely situated on a fiorde or arm of the sea, from which rises hills on three sides, on which the city is built, and from the sea resembles an amphitheatre. It contains 1208 houses and 13,109 inhabitants. It is a place of great trade and manufactures, the chief port to which ships from the West Indies repair. The manufactures are numerous, being assisted by good water power. There are several institutions for education and for charitable purposes, and some delightful promenades and prospects. Long. 9. 21. E. Lat. 51. 17. N.

FLESH, in *Anatomy*, a compound substance, consisting of the various softer solids of the animal body, and so denominated in contradistinction to bones. See ANATOMY, *passim*.

FLETA, the name given to an unknown writer who lived about the end of the reign of Edward II. and beginning of Edward III. and who, whilst a prisoner in the Fleet, wrote an excellent treatise on the common law of England.

FLETCHER. See BEAUMONT AND FLETCHER.

FLETCHER, *Andrew*, of Saltoun, a celebrated Scottish patriot and political writer, was descended from an ancient family, who traced their origin to some one of the followers of William the Conqueror. He was the son of Sir Robert Fletcher of Saltoun and Innerpeffer, and was born in the year 1650. The tuition of young Fletcher was committed by his father, on his deathbed, to Mr, afterwards Bishop, Burnet, then his parish minister, to whose care and attention he was indebted for a pious, learned, and polite education. Being endowed with uncommon genius, and possessed of virtues and abilities peculiarly suited to the times in which he lived, Mr Fletcher quickly shone forth the ornament of his country and the champion of its freedom. Having in the course of his classical studies and historical reading been impressed with an enthusiastic admiration both of ancient and modern republics, he had early contracted an ardent love of liberty, and an aversion to arbitrary rule. Hence his spirit the more readily took alarm at certain measures in the reign of Charles II. Being knight of the shire for Lothian to the parliament where the Duke of York appeared as commissioner, he openly opposed the designs of that prince and the bill of accession; and he had a share with Lord Viscount Stair in framing the test act, by which the Duke of York complained that he had lost Scotland. On these accounts he became peculiarly obnoxious to his royal highness, and was at last obliged to fly to Holland, to avoid the fatal consequences of prosecutions which on various pretences were commenced against him. Being cited before the privy council and justiciary courts, and not appearing, he was declared a traitor, and his estate confiscated.

In Holland, Fletcher and Baillie of Jerviswood were the only persons whom the Earl of Argyll consulted concerning the designs which were then in agitation. In 1681 they came over to England in order to concert matters with their party in that country; and they were the only persons who were entrusted so far as to be admitted to the secrets of Lord Russell's council of six. Mr Fletcher managed his part of the negotiation with so much address, that the administration could find no pretext for seizing him; nor could they fix upon him those articles on account of which Baillie was condemned; and to the honour of the latter be it remembered, that although offered a pardon on condition of accusing his friend, he persisted in rejecting the proposal with indignation.

Mr Fletcher having joined the Duke of Monmouth upon his landing, received a principal command under him; but the duke was deprived of his services owing to a circumstance which is related by Sir John Dalrymple. Being sent upon an expedition, and not esteeming "times of danger to be times of ceremony, he had seized for his own riding the horse of a country gentleman (the mayor of Lynne), which stood ready equipped for its master. The master, hearing this, ran in a passion to Fletcher, gave him opprobrious language, shook his cane, and attempted to strike. Fletcher, though rigid in the duties of morality, having been accustomed to foreign service both by sea and land, in which he had acquired high ideas of the honour of a soldier and a gentleman, and of the affront of a cane, pulled out his pistol and shot him dead on the spot. The action was unpopular in countries where such refinements were not understood. A clamour was raised against it among the people of the country; in a body they waited upon the duke with their complaints; and he was forced to desire the only soldier, and almost the only man of parts, in his army, to abandon him. With Fletcher all Monmouth's chance of success in war left him." In a manuscript memoir belonging to the family there is the following notice concerning Mr Fletcher's connection with Monmouth, in which his separation from that prince is very differently accounted for: "To Lord Marischal Mr Fletcher explained the motives which first induced him to join, and afterwards abandon, the Duke of Monmouth. The former he ascribed to the duke's manifesto in Scotland relating to religion, and in England to liberty. For the latter he accounted by the disgust produced in his own mind, and that of his associates, when the duke declared himself king, and broke faith with all who had embarked with him on his principles. He complained heavily of the account commonly given of the death of the mayor of Lynne; and mentioned to Lord Marischal, in proof of the contrary, that he did not leave the duke till he came to Taunton, where he was proclaimed king, several weeks after the death of the mayor of Lynne."

Seeing all the efforts of his friends and of himself in favour of liberty frustrated at Taunton, he endeavoured to secure his own personal freedom by taking his passage in the first ship bound to a foreign country. It was his misfortune, however, to land in Spain, where he was immediately arrested, cast into prison, and guarded by three different bands of soldiers, till a vessel could be prepared to carry him a victim in chains to the court of London. But on the morning upon which the ship was to sail, whilst he looked pensively through the bars of his window, he was hailed by a venerable personage, who made signs to speak with him. The prison doors he found open; and whilst his friendly conductor motioned to him to follow, he passed through three different guards of soldiers all fast asleep. Without being permitted to offer his thanks to his deliverer, he found himself obliged to prosecute with all speed his journey, in which he was directed by a person concerning whom he could never collect any information, and thus he proceeded in safety through Spain.

During his exile he maintained a frequent and extensive correspondence with the friends of liberty at home, and he partly employed himself in making a curious collection of books. But his genius also prompted him to engage in more active employments. He repaired to Hungary, and served several campaigns with much reputation as a volunteer under the Duke of Lorrain. At length, understanding that the great design then projected in Holland, and upon the issue of which he considered the liberties of Britain to depend, had obtained a considerable degree of maturity, he hastened thither, and his counsels and address were of eminent service to the cause. He came over with King William; and in zeal, activity, penetration, and political skill, proved inferior to none of the leaders in the Revolution.

Such, however, was his magnanimity, that whilst others laboured to render this grand event a source of emolument to themselves and aggrandisement to their families, Mr Fletcher asked for nothing. His estate had been forfeited, and his house abandoned to military execution; his fortune was greatly shattered, and his family reduced to circumstances of distress; yet nothing was given him in recompense of all his sufferings. On the contrary, he had the honour, along with the Duke of Hamilton, to be distinguished by marks of both royal and ministerial dislike. Still, whatever private resentment he might entertain, his ruling principle was the good of his country, and to this grand object of his heart he was willing to sacrifice all personal considerations. Accordingly, in 1692, when the abdicated king meditated an invasion, Mr Fletcher addressed a letter, preserved in Sir John Dalrymple's collection, to the Duke of Hamilton, in which every argument is employed with skill and energy to engage his grace to forget his injuries, and in the actual crisis to employ the extensive influence which he then possessed in the cause of freedom and of his country. This letter produced its full effect, and the duke returned to his duty, from which he had in some degree begun to estrange himself.

To follow our author throughout all the mazes of his political life subsequently to the Revolution, is beyond our purpose, and would exceed our limits. It will be sufficient to mention one or two additional circumstances illustrative of his character. Being elected a member for the parliament 1693, he showed an uniform zeal for the interest of his country. The thought of England domineering over Scotland was what his generous soul could not endure. The indignities and oppression which Scotland lay under galled him to the heart; and in his learned and elaborate discourses he exposed them with undaunted courage and affecting eloquence. In that great event, the Union, he performed essential service. He got the act of security passed, which declared that the two crowns should not be placed on the same head until Scotland had been secured in her civil and religious liberties. After the queen's demise, therefore, Lord Godolphin was forced into the Union, in order to avoid a civil war. Although Mr Fletcher disapproved of some of the articles, and indeed of the whole frame of the Union; yet, as the act of security was his own work, he had all the merit of that important transaction.

We must not omit mentioning, that in the ardour of his political career Mr Fletcher forgot not the interests of the place which gave him birth. He esteemed the education of youth as one of the noblest objects of government. On this subject he wrote a treatise, still extant, which is most characteristic of himself; and he established at Saltoun a foundation for the same purpose, of great utility while it lasted. This remarkable person died at London in 1716, at the age of sixty-six, and his remains were conveyed to Scotland, where they were deposited in the family vault at Saltoun.

Mr Fletcher was master of the English, Latin, Greek, French, and Italian languages, and well versed in history, the civil law, and other kinds of learning. In his travels he had not only acquired considerable knowledge in the art of war, but had also become conversant with the respective interests of the several princes and states of Europe. In private life he was affable to his friends, and free from all manner of vice. He had a penetrating, clear, and lively apprehension; but is said to have been too much wedded to opinions, and impatient of contradiction. He was by far the finest speaker in the parliament of Scotland, and the Earl of Stair alone rivalled him. The latter was famed for a splendid, the former for a close and nervous eloquence.

In 1698 he published a *Discourse on Government with Relation to Militias*, and two *Discourses concerning the Affairs of Scotland*. These and some other pieces, together with a few of his speeches, were after his death collected and published in an octavo volume, entitled *Political Works of Andrew Fletcher, Esq.*

FLETCHER, *Phineas*, an English poet who enjoyed considerable popularity in his own day, but regarding whom few particulars have descended to posterity. He was the son of Dr Giles Fletcher, who, on account of his abilities, was entrusted by Queen Elizabeth with several important missions, especially one to Russia, in which he negotiated a treaty highly advantageous to England. He published an account of *The Russe Commonwealth*, which was at first suppressed, but afterwards reprinted in 1643. Phineas, his eldest son, was educated at Eton, and in 1600 was elected to King's College, Cambridge, where he took the degrees of bachelor and master of arts. Having entered into holy orders, he received the living of Hilgay in Norfolk in thé year 1621. It appears from Blomefield's *Norfolk*, that he continued to officiate in his clerical capacity for twenty-nine years, and it is probable that he died here. These are all the facts known regarding Phineas Fletcher, a poet who was styled "the Spenser of his age," but whose fame is scarcely equal to his merit. He wrote *Sicelides*, a piscatory drama, which was printed anonymously in 1631. In the year following he printed at Cambridge a work entitled *De literatis antiquæ Britanniæ, præsertim qui doctrina claruerunt, quique collegia Cantabrigiæ fundarunt*, 12mo. In the year following he printed, in one vol. 4to, his *Purple Island*, *Piscatory Eclogues*, and *Miscellanies.* These poems have all been reprinted, but not frequently. They are, however, to be found in Anderson's *British Poets*.

The character of Phineas Fletcher appears to have been mild and amiable, and his contemporaries passed liberal encomiums upon him for his learning and piety. As a poet he possesses more merit than posterity seems disposed to attribute to him. The *Purple Island* is his longest and his best production. It is an allegorical poem, of which man is the subject. The first five cantos may be entitled the anatomy of the human body in rhyme. In the remainder of the poem the poet quits the dissecting-room for the academic grove of intellectual philosophy, and the learning of the schools. Although the design is bad, and the reader sickens over anatomical details and abstract subtilties, it is impossible not to admire the ingenuity with which the writer has invested them with the flowers of fancy and of poetry. There is a profusion of images; and although, as might have been expected, many of his allegorical personations are too elaborately drawn and too highly coloured, some of them are distinguished by a boldness of outline, a majesty of manner, a brilliancy of tint, a propriety of attribute, and an air of life, which are rarely met with in modern productions, and rival the best things of the kind even in Spencer, the author from whom he caught his inspiration. Too often, indeed, his conceptions are incongruous, and his conceits fantastical; but many beautiful thoughts are interspersed throughout, and the whole is enriched with a vein of genuine poetry.

FLETCHER, *Giles*, brother of the preceding, and of whom also few memorials remain, was born in the year 1558. He was bred at Cambridge, and died at his living at Aldenston in Suffolk, in the year 1623. He is principally known as the author of *Christ's Victory and Triumph over and after Death*, a poem characterized by a tone of enthusiasm peculiarly solemn. Like his brother, he was an imitator of Spencer, and, with the diction of the latter slightly modernized, he retains much of his melody and luxuriant expression. Giles Fletcher, there can be no doubt, is inferior both to Spencer and Milton, but he frequently reminds us of both; and it seems evident that the latter was indebted to him for hints, particularly with reference to *Paradise Regained;* and some of the finest parts of *Paradise Lost* appear likewise to have been suggested by passages in *Christ's Victory and Triumph*. Although in several parts rather fantastical and quaint, that poem is a fine effusion of genius, and one of the best productions of the kind in the language.

FLETEWOOD, WILLIAM, an eminent English lawyer and recorder of London in the reign of Queen Elizabeth. He was very zealous in suppressing mass-houses, and in imprisoning Roman Catholic priests; but having once rushed in upon mass at the Portuguese ambassador's house, he was committed to the Fleet for breach of privilege. Mr Wood says he was a learned man and a good antiquary, but of a marvellous merry and pleasant conceit. He was a good popular speaker, and wrote well upon subjects of government. His principal works are, 1. *Annalium tam regum Edwardi V. Richardi III. et Henrici VII. quam Henrici VIII.;* 2. *A Table of the Reports of Edmund Plowden;* 3. *The Office of a Justice of Peace.* He died about the year 1593.

FLEURY, CLAUDE, sub-preceptor of the young princes of France, was the son of an advocate before the council, originally from Rouen, and born at Paris on the 6th of December 1640. He studied under the Jesuits, in the College of Clermont, where he passed six years; and he ever afterwards cherished sentiments of the liveliest gratitude towards his kind and able masters. Being intended by his father for the bar, he now applied himself to the study of the civil law and of history, to which he added the belles-lettres, for which he had a strong predilection, and he was admitted as an advocate before the parliament of Paris in 1658. He remained at the bar nine years, during which time the peaceable life he led, a natural taste for solitude, and religious sentiments, the fruits of his early education, insensibly produced in his mind an inclination for the church. As soon as his resolution was fixed, he made a corresponding change in his pursuits, and the works which had hitherto been the objects of his study were replaced by theology, the fathers, ecclesiastical history, and the canon law, in all which he became very learned. He had already been some time in priest's orders, when, in 1672, he was chosen, on account of his merit, as preceptor to the sons of the Prince of Conti, who were educated along with the dauphin. At the expiration of this engagement, the king, who had occasion to observe and appreciate his merit, entrusted him with the education of the Count of Vermandois, which, however, he did not complete, as this young prince died in 1683. In 1684, the king conferred on him the abbey of Loc-Dieu, belonging to the order of Citeaux; and in 1689, appointed him sub-preceptor to the Dukes of Burgundy, Anjou, and Berry. The Abbé Fleury having thus found himself associated with Fénélon, shared the labour which that illustrious prelate bestowed on the education of his august pupils, and contributed essentially to its success. It was in 1696, whilst he was still occupied with the instruction of the princes, that he was named one of the forty of the French Academy to fill the place of La Bruyère. In other respects he led as retired a life at court as he could have done in the most profound solitude. Entirely occupied with the duties of his office, to which he devoted himself without reserve, he had but few moments of leisure; but these, when he could command them, were given to useful pursuits. When the education of the princes was completed, Louis, who not only knew how to distinguish talents, but also how to reward them, conferred on Fleury the rich priory of Argenteuil; upon which the abbé, faithful to the discipline established by the canons, resigned his abbey into the hands of the king. It was then that, free from all care, he devoted himself entirely to pursuits worthy a man of his station; but Louis XIV. having died, in 1716, he was recalled to the court by the regent, to become confessor to the young king. In appointing him to this office the regent is reported to have said, "I have chosen you because you are neither Jansenist, nor Molinist, nor Ultramontanist." Fleury discharged with zeal and sagacity the delicate functions of his new situation, which, however, he resigned in 1722, by reason of his great age. He died on the 14th of July 1723, in his eighty-third year. Fleury was alike remarkable for his great learning and extreme simplicity of manners; in him Christian humility was blended with true dignity, and the gentlest disposition with the loftiest spirit. He was mild, affable, benign, charitable; an ardent lover of truth, and a bright pattern of those virtues which he inculcated on others. His understanding, naturally excellent, was cultivated with infinite labour; and his heart was as carefully disciplined as his understanding. Profound knowledge, sterling rectitude of principle, innocent manners, a simple, laborious, and edifying life, sincere modesty, admirable disinterestedness, unfailing regularity, and the utmost fidelity in the discharge of all his duties; such are the traits of the character of Fleury as delineated by his contemporaries; a character which, in their judgment, exhibited an assemblage of all the talents and virtues which form the profound scholar, the honest man, and the devout Christian. The following is a list of the numerous works which he left behind him, part of which were composed during brief snatches of leisure, whilst occupied with the education of his different royal and noble pupils: 1. *Histoire du Droit Français*, 1674, in 12mo; 2. *Catéchisme Historique*, Paris, 1679, in 12mo; 3. *Les Mœurs des Israélites*, Paris, 1681, in 12mo; 4. *Les Mœurs des Chrétiens*, 1682, in 12mo; 5. *La Vie de la vénérable mère Marguérite d'Arbouze, abbesse et reformatrice du Val-de-Grâce*, Paris, 1684, in 8vo; 6. *Traité du choix et de la méthode des Etudes*, Paris, 1686, in 12mo; 7. *Institution au Droit Ecclésiastique*, Paris, 1687, in 2 vols. 12mo; 8. *Les Devoirs des Maîtres et des Domestiques*, Paris, 1688, in 12mo; 9. *La Traduction Latine de l'Exposition de la Doctrine de l'Eglise Catholique par Bossuet*, Antwerp, 1678, in 12mo; 10. *Histoire Ecclésiastique*, Paris, 1691 and the following years, in 20 vols. 4to, continued by Père Fabre, of the Oratory, Paris, 1726 and the following years, in 16 vols. 4to, making in all 36 vols. 4to; 11. *Discours sur l'Histoire Ecclésiastique*, Paris, 1802, in 8vo; 12. *Discours sur les Libertés de l'Eglise Gallicane*, 1724. Besides these works, the Abbé Fleury was also the author of the following, viz. 1. *Discours sur la Prédication*, 1773, in 12mo; 2. *Traité du Droit publique de France*, 1769, in 4 vols. 12mo; 3. *Le Soldat Chrétien*, 1772, in 12mo; 3. *Lettres à Santeul, et deux Lettres en vers Latins*; 4. *Discours sur la Poésie et notamment sur celle des Hébreux*; 5. *Portrait du Duc de Bourgagne, et Avis pour ce Prince*; 6. *Réflexions sur Machiavel*; 7. *Lettres sur la Justice*; 8. *Pensées tirées de Saint-Augustin*; 9. *Mémoires pour le Roi d'Espagne*; 10. *Discours Académiques*. All the works of the Abbé Fleury, with the exception of the Ecclesiastical History, were collected by Rondet, under the titles of *Opuscules*, Nismes, 1780, in 5 vols. 8vo; but M. Emery, superior-general of the Congregation of Saint-Sulpice, published a volume entitled *Nouveaux Opuscules*, Paris, 1807, in 12mo, containing several unedited pieces, some of them possessing considerable merit.

FLEURUS, a small town of the province of West Flanders, in the circle of Charleroy, containing 600 inhabitants, and remarkable for the battles fought there in 1622, 1690, 1794, and 1815, though the last is more frequently designated the battle of Ligny.

FLEXIBLE, in *Physics*, a term applied to bodies capable of being bent or deflected from their natural figure or direction.

FLEXOR, in *Anatomy*, a name applied to several muscles, which are so called from their office, which is to bend the parts to which they belong, in opposition to the *extensors*, which open or stretch them.

FLINDERS ISLAND, is an island in the form of an irregular quadrangle of from three to five miles each side on the south coast of New Holland. Seals are numerous on the beach, and a species of kangaroo not larger than a cat is also found there. Long. 134. 27. E. Lat. 33. 41. S.

FLINT, a mineral which is principally composed of silica. See MINERALOGY.

FLINT, the county town of Flintshire, in North Wales, 204 miles from London, on the river Dee. It is an ancient corporation, and, in conjunction with the boroughs of Rhyddlan, Overton, Caerwys, and Caergoety, returns one member to the House of Commons. It is resorted to in summer for sea-bathing. Though the assizes are held at Mold, the county jail is at Flint. The population amounted in 1801 to 1169, in 1811 to 1433, in 1821 to 1612, and in 1831 to 2216.

FLINTSHIRE, a county of North Wales. It consists of a narrow tract of land, about twenty-eight miles in length, but varying considerably in its breadth, though in no part exceeding ten miles. The Irish Sea partly bounds it on the north; the river Dee and part of Cheshire on the north and north-east side; and the county of Denbigh on the south and west sides. A portion of the county is detached from the rest by the interposition of a part of Denbighshire. It is divided into five hundreds, viz. Coleshill, Maylor, Mold, Prestatyn, and Rhyddlan. The river Dee formerly washed the walls of the ancient castle of Flint, the county town, but has of late considerably receded, and it has now no means of carrying on commerce by sea, except in very small vessels; and it is necessary that those should be so constructed as to remain dry, during low water, without injury. Mold, the town at which the assizes are held, has rapidly increased, owing in some measure to the establishment of very extensive mills for spinning cotton in its vicinity. The city of St Asaph is neither distinguished by its extent nor the beauty of its buildings. Its situation, on the side of a hill, the summit of which is crowned by the cathedral, and between the rivers Clwyd and Elwy, is very imposing, and strikes the traveller forcibly as he approaches it. Though the immediate vicinity of this city has a sterile appearance, yet the views near it in one direction over the enchanting vale of Clwyd, and in another over the diversified landscape which terminates with the ruins of the castle of Denbigh, present to the eye of those who have a taste for beautiful scenery a most delightful treat.

The diocese of St Asaph extends nearly over the whole of the county, and, from several livings which are held *in commendam* by the bishop, is a very lucrative preferment. The Episcopal chair has, since the Reformation, been filled by many prelates of most distinguished character. Morgan was translated to this see in 1601, as a reward for his eminent acquirements as an oriental linguist. He was employed in translating the sacred writings into the Welsh language, as well as in a part of the English edition commonly called Queen Elizabeth's Bible. Dr Isaac Barrow, uncle to the celebrated mathematician, was eminent for his munificence to the see, as well as for his profound learning. The pious Beveridge, during a few of his last years, was bishop of St Asaph; and the chair has been since filled by the amiable and learned Shipley, and the powerful and energetic Horsley. The cathedral has been of late much improved and beautified by the bounty of Bishop Bagot, and the liberal contributions of the nobility and gentry of the county. It was built about the year 1480, upon a foundation of much more ancient date; it is in length from east to west 179 feet, and in breadth from north to south 108 feet. The most important place in this county, from its wealth, its population, and its continued increase, is the town of Holywell, deriving its name from the well of St Wenefrede, which, in the ages of credulity, was supposed to possess miraculous powers of healing, but has of late been applied to better purposes than nurturing such superstitions. As there are many Catholics in Flintshire, the belief in the miraculous power of this spring is not wholly extinct, nor have the pilgrimages to it altogether ceased. So late as 1805, indeed, a very zealous attempt was made to revive the credit of the saint, and establish faith in the wonderful cures achieved by bathing in her well. A case was narrated, accompanied with certificates, and a challenge given to all who doubted of the miracle, by an appeal to facts which, however it might confirm the faith of the saint's votaries, had no influence beyond that narrow circle.

The productions of Flintshire which deserve most notice are the minerals, the preparation of which gives employment to a considerable share of the population. Coals are found in abundance, chiefly near the banks of the Dee, and in other parts near the surface, and in very thick seams. The city of Chester is principally supplied with its fuel from hence, and considerable quantities were shipped for Ireland before the change in the course of the Dee, and before the coal mines of Lancashire and Cumberland had attained their present extent. Lead is most copiously raised from a very extensive mining tract near Holywell; and in the same excavations is raised most excellent limestone, applicable to the purposes of agriculture as well as building, and so hard that it will bear a high polish, in fact a kind of marble. Below the limestone is found petrosilex, which is ground and becomes very valuable in the manufacture of earthenware. Calamine is found in considerable quantities; a part is exported, but much is used within the county in the preparation of brass. The lead is divided by the miners into two kinds; that called cubic, or dice ore, is generally used in glazing earthenware; the other, called white, or steel-grained ore, is principally cast into pigs for distant consumption: this latter contains a portion of silver sufficient to defray the expense of separating the metals, and several thousand ounces have been annually extracted. The workmen in the lead mines are visited with maladies which both embitter and shorten their lives.

The manufactories of this county are very considerable, and have taken that course which the natural productions seem to have indicated. Brass is made by the mixture of copper with calamine, and formed into the different shapes to fit it for domestic and commercial purposes. Copper-works, under the Pargs Mine Company, are constructed, and produce large quantities of copper sheathing, bolts, nails, and other necessaries for naval equipment, as well as brass wire and minuter articles. The potteries are very extensive, and manufacture large quantities of the inferior kinds of earthenware, which supply the consumption of a great part of Wales, and export considerable quantities to Ireland. Besides those manufactories which the minerals have introduced, the fine stream that issues from the well of St Wenefrede has attracted the attention of cotton-spinners, who have erected a most powerful mass of machinery. They carry on the operations of carding and spinning cotton to a great extent.

The agriculture of this county is in a neglected state, drawing to it a very insufficient portion of its capital; and hence few improvements have been adopted of late years. Near the banks of the Dee there is some good corn land, of a clayey texture, on which, after a fallow, good wheat is grown. The meadows in this part produce excellent herbage, and the cows afford the best possible butter. The northern part of the county is generally a level country, and well calculated for the growth of wheat, oats, and beans. On the higher lands rye is cultivated, but those lands are very imperfectly tilled, and nearly destitute of manure. The rich vale of Mold forms a striking contrast with the more mountainous parts of the county, and yields very good butter, corn, and meat.

The ruins of ancient edifices, and other antiquities, are numerous, and invite the attention of the antiquarian. A few years ago, whilst digging for the purpose of laying the foundation of a copper work, a Roman *hypocaust*, or hot bath, was discovered, furnished with numerous flues, covered with tiles of a red colour; a clear evidence that the county had been anciently inhabited by some persons acquainted with the luxuries of Rome.

Few counties, in proportion to their extent, contain so many gentlemen's seats as Flintshire. The most remarkable are, Mostyn Hall, Sir Thomas Mostyn; Pengewern, Sir Edward Pryce Lloyd; Boddlewyddan, Sir John Williams; Kinmael Hall, Reverend Edward Hughes; Gwernhailed, Philip Lloyd Fletcher, Esq.; Hanmer Hall, Sir Thomas Hanmer; Downing, David Pennant, Esq.; Halken, Earl Grosvenor; Adwynt, J. Roberts, Esq.; Llewenny Hall, Lord Kirkwall.

The following are the returns of the population for the years ending 1811, 1821, and 1831.

YEARS.	HOUSES.			OCCUPATIONS.			PERSONS.		
	Inhabited.	By how many Families occupied.	Uninhabited.	Families chiefly employed in Agriculture.	Families chiefly employed in Trade, Manufactures, or Handicraft.	All other Families not comprised in the two preceding classes.	Males.	Females.	Total of Persons.

See *Agricultural Survey of North Wales;* Wynne's *History of Wales;* Aikin's *Tour in North Wales.* (G.)

FLIP, a sort of drink, composed of malt liquor, brandy, and sugar, and in great favour among sailors.

FLOAT, a certain quantity of timber bound together with rafters athwart, and put into a river to be conveyed down the stream.

FLOATING BODIES are those which swim on the surface of a fluid, the most interesting of which are ships and vessels employed in commerce and war. See SHIP-BUILDING.

FLOOD, a deluge or inundation of waters. See the article DELUGE.

FLOOD is also used in speaking of the tide. When the water is at the lowest, it is called *ebb;* when rising, *young flood;* when at the highest, *high flood;* when beginning to fall, *ebb water.*

FLOOD-mark, the mark which the sea makes on the shore at flowing water and the highest tide. It is also called *high-water mark.*

FLOOR, in building, the underside of a room, or that part which we walk on. See BUILDING.

FLORA, the reputed goddess of flowers, was, according to Lactantius, only a lady of pleasure, who having gained large sums of money by prostituting her person, made the Roman people her heir, on condition that certain games called *Floralia* might be annually celebrated on her birthday. Some time afterwards, however, such a foundation appearing unworthy the majesty of the Roman people, the senate, in order to ennoble the ceremony, converted Flora into a goddess, whom they supposed to preside over flowers, and thus made it a part of religion to render her propitious, that it might be well with their gardens, vineyards, and parterres. But Vossius (*De Idol.* lib. i. c. 12) is by no means disposed to allow the goddess Flora to have been the courtezan above mentioned; he contends that she was a Sabine deity, and thinks that her worship might have commenced under Romulus. His reason is, that Varro, in his fourth book of the Latin tongue, ranks Flora amongst the deities to whom Tatius king of the Sabines offered up vows before he joined battle with the Romans. The goddess Flora was, according to the poets, the wife of Zephyrus. Her image in the temple of Castor and Pollux was dressed in a close habit, with the flowers of peas and beans in the hand; but the modern poets and painters have been more lavish in setting off her charms, considering that no parts of nature offered such innocent and exquisite entertainment, as the beautiful variety which adorns, and the odour which embalms, the floral creation.

FLORAC, an arrondissement of the department of the Lozère, in France, extending over 660 square miles. It is divided into seven cantons, and these into fifty-five communes, containing 43,500 inhabitants. The capital is the town of the same name situated on the river Tornou, which falls into the Tarn. It contains 340 houses, with 2160 inhabitants.

FLORALES Ludi, or Floral Games, in *Antiquity*, were games celebrated in honour of Flora, the goddess of flowers. The *ludi florales*, according to Pliny (lib. xviii. c. 29), were instituted by order of an oracle of the Sibyls, on the 28th of April; not in the year of Rome IↃXVI. as we commonly read it in the ancient editions of that author, nor in IↃXIV. as Hardouin has corrected it, but, as Vossius reads it, in 513; though they were not regularly held every year till after 580. They were chiefly held in the night time, in the patrician street; but some will have it there was a circus for the purpose on the hill called Hortulorum.

FLORALIA, in *Antiquity*, a general name for the feasts, games, and other ceremonies, held in honour of the goddess Flora.

FLORENCE, a city, the capital of the grand duchy of Tuscany, and of the division of it of the same name. The department of Florence comprehends the extensive valley of the Arno, and a great portion of the Appennine Mountains, and extends over 3652 square miles, divided into thirty-three vicariates, and containing 643,385 inhabitants. The city of Florence is at the foot of the Appennines, in a beautiful and fertile valley, and is watered by the Arno, which divides it into two unequal parts. It is surrounded with fortifications, but of no great military strength. It has seven gates, of which that of St Gallo is distinguished by a noble marble triumphal entrance. It is divided into four wards, and contains seventeen piazzas, 172 churches, twelve hospitals, many noble private palaces, 9000 dwellings, and 75,200 inhabitants. The streets are not altogether regular or wide, but they are kept clean, are well paved, and lighted by night. The Via Larga is distinguished by many large and magnificent palaces; but the Corso, in which races are held, is the favourite promenade of the fashionable people. The finest view of the city is, however, to be seen from the piazza of Santa Maria to the palace Pitti, the grand ducal residence. The cathedral, the galleries, the churches, the obelisks, and the fountains, are the most magnificent of any in Italy, and deserve a description more detailed than the compass of this notice will allow. The institutions for charity, and the establishments for instruction, especially in the fine arts, are upon an extensive and liberal plan. There are three public libraries; the Laurenziana with 120,000 volumes, the Machlibecchiana with 90,000, and the Marcelliana with 40,000. Florence was formerly one of the most distinguished manufacturing places of Italy, and the various kinds of silk goods and of fine black cloth there produced still maintain a high reputation. Besides these, it produces table and other linen, woollen cloths, carpets, caps, soap, perfumery, and essences, lacquered and silvered ware, and many works in alabaster and marble. Florence has produced many individuals eminent in arts, science, and literature; among others, Machiavelli the political writer; Dante Allighieri, Luigi Rucellai, Menzini, and Filicaja, poets; Guicciardini the historian, Michel Angelo Buonarotti the artist, Galileo the astronomer, Amerigo Vespuccio the navigator, Lully the musician, and the artists of the school of this city. It is in long. 11. 0. 25. E. lat. 43. 46. 30. N.

Florence, an ancient piece of English gold coin. Every pound weight of standard gold was ordained to be coined into fifty Florences, to be current at six shillings each; or into a proportionate number of half Florences, or quarter pieces, by indenture of the mint. See 18 Edw. III.

FLORES, or Ende, an island in the Eastern Seas, extending about 200 miles in length by forty or fifty in breadth, at the extremity of which is a strait called Flores Strait. Near the coast is a fine open country, but the interior parts are mountainous and woody; and there is said to be a volcano in the centre. Sandal wood was formerly obtained here in great abundance, but it is now grown scarce. At a village in the straits which separate Flores from Sabraon and Solor, European vessels procure refreshments in exchange for ammunition, coarse cutlery, and other articles. The island belongs to the sultan of Beema, in the island of Sambawa, who derives a considerable revenue from the edible bird-nests found in it. The Portuguese formerly resided in it; and their descendants, or those calling themselves such, and professing the Roman catholic religion, are still dispersed over the island. The island is situated between the 120th and 123d degrees of east longitude, and the 8th and 9th degrees of south latitude.

FLORIDA, a country of North America, now belonging to the United States. It is about 450 miles in length, and has an average breadth of about 120 miles. It is comprehended between the parallels of 80. 25. and 87. 20. W. long. and 25. and 31. N. lat. Formerly it was separated into two political divisions, whose geographical limits were strongly marked by nature, viz. East and West Florida. But this division has ceased to exist, and the two Floridas now constitute one government. It is bounded on the north by Alabama and Georgia, on the east by the Atlantic Ocean, and on the south and west by the Gulf of Mexico. The northern part of the western boundary is formed by the river Perdido, which separates it from Alabama. Florida formerly extended as far west as the Mississippi, the northern boundary being formed by St Mary's River from the ocean to its source, thence by a right line to the point where Flint River unites with the Appalachicola, thence up the Appalachicola to the parallel of lat. 31. N. and thence due west on that parallel to the Mississippi. The part lying between the Mississippi and Pearl River is now included in the state of Louisiana; and the part between the Pearl and the Perdido, in the states of Mississippi and Alabama. The part east of the Perdido is under the territorial government of Florida. It is supposed that this country contains about twenty-four millions of acres of marketable land.

It is now generally admitted that Florida was discovered in 1497 by Sebastian Cabot. In 1512, however, it was more fully explored by the Spaniards under Juan Ponce de Leon, who gave this region its name from *Pasqua Florida*, or Palm Sunday, probably the day on which land was descried. For a long time the name was general, in Spanish works, for the whole Atlantic coast of North America. The first effectual settlement of the country was made in 1524. Four years afterwards an expedition was undertaken by Pamphilo de Narvaez, with 400 men, from the island of Cuba. He penetrated into the interior of the country, but was never heard of more. In 1538 Florida was entirely subdued by Fernan de Soto, an officer in the Spanish service, after a long and bloody struggle with the natives. In 1564 the French also obtained a footing in the country, owing to the facility with which they gained the good will of the natives, and the readiness which the latter displayed in assisting them against the Spaniards. They formed little settlements along the shore, but these were ultimately destroyed by the Spaniards. In 1597 the French made severe reprisals against their European enemies, but from this time they abandoned their settlements in this part of North America. In 1586 the town of St Augustine was attacked and pillaged by Sir Francis Drake; and in 1665 it was also entered and plundered by a body of bucanneers under Captain Davis. In 1702, Colonel More, with a body of troops, besieged this town for three months; but the Spaniards having come to its relief, he was compelled to retreat. Another attempt to take St Augustine was made in 1740, but without success. In 1763 Florida was ceded to Britain by Spain, which received Havannah in exchange. The British government gave great encouragement to agriculture, and numerous colonists poured into the country from various parts of Europe, as well as from Great Britain. This is regarded as the most flourishing period in its history. It was, however, by a well-concerted scheme of the Spaniards, reconquered in 1781, and guaranteed to them by the peace of 1783. In 1819 negotiations were commenced between the United States and Spain, for the cession of Florida to the former; and a treaty to that effect was entered into. This treaty was ratified shortly afterwards, and in July 1821 Florida was finally taken possession of by General Jackson, by order of the government of the United States, to which it now entirely belongs.

As the whole province is a peninsula, it presents an extended point to the sea, and from its position, as well as its formation, is calculated, when peopled, to enjoy a considerable share of navigation; but the want of secure bays and harbours, and the dangerous bars at the mouths of its rivers, will prevent any sanguine expectations of its speedy pre-eminence from being realized.

From the uncommon flatness of the country on the sea shore, and from its being intersected by numerous rivers, there is perhaps no part of the world of the same extent which has so many inlets, sounds, narrow passes of water between the islands, and communications of one point of the shore with another by means of inland channels. The whole coast is almost a continued line of these sounds; and it is contemplated that, at a comparatively small expense, a canal, communicating with the sea in a hundred places, might be made from New Orleans to the river St Mary. Almost all the rivers, before discharging themselves into the gulf, spread into broad lakes, which are frequently joined by a natural canal, containing from four to six feet of water. Perdido Bay, which divides Alabama from Florida, is thirty miles in length and from two to six in breadth. Pensacola Bay is of about the same length, but of greater breadth; it receives several rivers, and affords the best harbour on the whole shores of the gulf. Chactawhatchee Bay is forty miles in length, and from seven to fifteen in breadth. It is connected with Pensacola Bay by St Rosa Sound, a fine sheet of water, about forty miles in length and from one and a half to two miles in breadth. There are a number of other bays, but of smaller dimensions than those above mentioned.

All the rivers which have long courses rise in the high lands of Georgia, Alabama, and Mississippi. St Marys, which is for a long way the separating line between Florida and Georgia, is a very considerable stream, which falls into the Atlantic by a broad mouth, but is only navigable for a short distance. St John's is also a large river; it rises in the centre of the peninsula, and flowing with a gentle current in a northerly direction, spreads into a wide channel, and passes through several lakes, the largest of which, St George, is twenty miles long and twelve broad, and finally falls into the sea forty miles to the south of St George. It has been navigated by a steam-boat. Most of the rivers which fall into the gulf have their sources in Georgia. The most important of these is Appalachicola, which divides East from West Florida. It is formed by the conjunction of two considerable streams, and is the longest, largest, and most important river in Florida. Besides those above mentioned, there are a great number of other rivers which fall into the gulf at different points. Indeed the whole country is intersected by them, and so furnished with inlets, and level in the soil, that there is no part of the territory at any considerable distance from water communication. The value of the rivers, however, is considerably depreciated by most of them having a bar at their mouth, which prevents vessels drawing much water from entering. But schooner and steam-boat navigation is practicable to a considerable extent.

The sea islands on the Florida shore are not of much importance. St Rosa island is a long and narrow slip parallel to the coast, between St Rosa Bay and Pensacola. The Tortugas are a group of islands opposite the southernmost point of East Florida; they are covered with mangrove bushes, and extend from north-east to south-west. Anastasia, which is opposite to St Augustine, and divided from the mainland by a narrow channel, is twenty-five miles in length. They are covered with pine trees and sand banks, and have a sterile soil. On the West Florida shore are Hummoch, Crooked, St Vincent's, St George's, Dog, and James' Islands.

There are a vast number of springs, fountains, and lakes in Florida. The subterranean waters frequently burst forth in the form of vast boiling springs, which form rivers at a short distance from their outlets, and by their frequency, their singular forms, the transparency of their waters, and the multitude of their fishes, constitute one of the most striking curiosities of the country. There is a spring or outlet of immense size situated about twelve miles from Tallahasse. It has a depth of about two hundred and fifty fathoms. The waters, like those of the gulf, have a cerulean tinge, and are of aerial transparency. Amongst the other curiosities of Florida may be mentioned a number of natural caverns and bridges, some of which are of considerable dimensions. The antiquities consist of great roads, causeways, forts, and other indications of former occupation.

The climate of Florida may be considered as in some respects tropical, but the northern belt of country, which lies along the southern limits of Georgia and Alabama, partakes of the cooler temperature of those states, and is remarkably salubrious. The regular range of the thermometer throughout Florida, from June to the autumnal equinox, is between eighty-four and eighty-eight degrees of Fahrenheit. The mercury occasionally rises to above 100°, but this seldom occurs. There is generally a sky of mild azure, a southern breeze, and an air of great purity; but even in winter the influence of the unclouded and almost vertical sun is uncomfortable. The evening air, however, is very humid, and the dews are excessive. In the peninsular parts there are sometimes slight frosts, but water seldom or never freezes. The most delicate orange trees bear fruit in full perfection, and of a delicious quality. The rainy season commences only in winter, and the sultry season begins in June and ends with the autumnal equinox. The peninsular parts being nearer the tropics, have a higher temperature than West Florida, which is occasionally fanned by Canadian breezes, sweeping the valley of the Mississippi. Like the West Indies, the peninsula is subject to tornados; and during the autumnal equinox hurricanes and destructive gales sometimes occur. There are in particular seasons indications of considerable humidity over the whole country; and the same sudden variations of temperature which constitute so distinct a feature in all the south-western parts of the United States are experienced here. The unremitting heat which prevails, and the frequent rains which fall from June to October, are apt to generate the fevers of southern climates, especially in places which lie in the vicinity of ponds and marshes. On the other hand, it may be safely asserted that those parts of Florida which are removed from swamps and other stagnant waters are healthy.

The lands of Florida, in their general character, are light and sandy; and they are represented as not capable of sustaining a continual succession of exhausting crops. Considerable tracts in different parts are fertile; but by far the greater part is sterile or unproductive. The lands have been divided into seven varieties: 1. *Pine Barrens*, which constitute a great part of the country. They produce vast quantities of yellow and pitch pine; also shrubs in great variety, and a wiry grass, which yields sustenance to numerous herds of cattle. In wet seasons, orchards of peach and mulberry trees flourish remarkably well on these lands. 2. *Hammock Land*. This variety, which constitutes the main body of good land, is so called because it rises in mounts or small tufts among the pines. Most of the islands remote from the sea are of this kind, which is adapted to sugar cane, cotton, indigo, potatoes, and pulse. 3. *Prairies*. These are of two kinds; one of them, found in the pine barrens, has a covering of sand, and is sterile; and the other, which is covered with wild grass, is met with on high lands. 4. *Swamps*. These are of two kinds, the river and inland swamps; the latter are the most valuable, producing rich crops of rice, and, in some instances, the best cotton, corn, and indigo, in the country. 5. *Marshes*, some of which are covered with salt water, and others with fresh. The fresh-water marshes produce an abundance of wild oats. 6. A species of marsh called *Gallen*, consisting of water courses covered with strong earth, which trembles like jelly when touched. 7. Elevated grounds covered with large trees of different species.

Florida is not rich in minerals, although it is affirmed that several kinds of precious stones have been found in it. Pit coal, iron ore, and ochres of different colours, are, however, abundant.

The vegetable kingdom in Florida displays greater variety than is to be found in any other part of the United States. In the hammock lands, on the river courses, and in the richer swamps, nothing can surpass the luxuriance and splendour of the trees and shrubs. Ever verdant forests of pine cover a great extent of country, and the trees are of uncommon height and beauty. What are called white cedar and cypress abound in the swamps, and they grow to an enormous size. Oaks are also numerous, and the tree here developes itself in full perfection. After the union of Florida with the United States, a plantation of oaks was commenced at Deer Point, and in 1829 upwards of 76,000 were growing in a flourishing condition. The cabbage palm, or *chœmarops palmetto*, is common, and grows to a great height. The leaves of this superb tree are manufactured into hats, baskets, and mats. In the deep swamps immeasurable cypress trees shoot up in straight columns, the foliage of which is closely interwoven at the top, forming a canopy of verdure of vast extent. On the hammock lands, the beautiful dog-wood trees spread their horizontal branches, which, interlacing each other, form a fine deep shade, impervious to the rays of the sun, and surpassing the growth of all vegetation underneath. Here also may be seen the beautiful pawpaw, which has a stem perfectly straight, smooth, and silver-coloured, with a conical top of evergreen foliage, and fruit of the richest appearance. Titi is the name of a shrub which fills the southern swamps, as the elder does those of the north. It flowers in masses of white ornamental blossoms, and has singular strings of covered seeds, which hang on the bushes till winter. Five or six species of pine are found here. The southern extremity of Florida is very rocky. Instead of the trees and shrubs which are found in the rest of the country, it is covered with mastic, lignumvitæ, gum elemy, ovino, wild fig, and mangrove.

There are many traces of ruined towers and Indian villages, together with other indications of former occupation; and wherever these are discovered, there may also be seen those groves of lime, orange, peach, and fig trees, which are spoken of by travellers as having been found here indigenous to the soil. Wild grape vines abound. *Myrica odorata*, or candle berry laurel, is common; and from the berries of this plant an excellent kind of wax for candles is prepared. Among other flowers is found the magnificent *Hybiscus*, which, though an herbaceous and annual plant, grows to the height of ten feet, branching regularly in the form of a sharp cone. It is covered with large crimson flowers, which unfold in succession during the whole of the summer months. *Tillandsia usneoides*, long moss or Spanish beard, is common here. It hangs down in festoons, sometimes from ten to fifteen feet in length, like the pendent stems of the weeping willow. The fibre, when properly prepared, is elastic and incorruptible, and in many respects resembles horse hair, both in appearance and use. It is used for stuffing cushions, saddles, and the like.

The low savannahs are covered, like the prairies of the upper country, with a prodigious growth of grass and flowers. In the swamps, the cane brakes are of great height and thickness, and the rushes, and other meadow plants, grow to an uncommon size. Some of the reed canes are seen from thirty to forty feet in height. The lakes and creeping bayous, especially in summer, are covered with a curious species of aquatic plant, called by botanists *pistia stratiotes*. It somewhat resembles the vegetable commonly called house-leek, and has a beautiful elliptical leaf. When the roots of thousands of these plants have twined together, so as to form a large and compact surface, the mass is often drifted by the wind or current to a considerable distance, and thus presents the appearance of a floating island of considerable extent. The herbarium of this country is exceedingly rich and diversified. The cultivated vegetables are, maize, beans, potatoes, especially sweet potatoes, pumpkins, melons, rice, and a variety of esculent roots, particularly a species of *arum*, which is not cultivated in the maritime parts. It has a large bulbous root, which, when roasted or boiled, has a taste similar to the yam. The pistache is a kind of nut in pods, which grows abundantly in sandy land. It is much cultivated both by the Seminoles (an Indian tribe) and by the Americans. It is baked or roasted in the shell, and used by confectioners as a sweetmeat. Tobacco, cotton, indigo, rice, and the sugar cane, will in future be the principal articles of culture. The African and Otaheite cane flourish remarkably well in the southern parts of the country, and planters are beginning to turn their attention to the cultivation of them. The coffee-tree has been tried on the peninsula; and coffee can unquestionably be raised there, but whether of a kind or in quantities which will justify an extensive cultivation of the article, has not yet been sufficiently proved. The olive, it has been found, flourishes here, and bears well. A species of cactus, on which the cochineal fly feeds, is common in the country. This plant, it is conjectured, will become an important article of manufacture. A species of cabinet wood of great beauty called bastard mahogany is also found here.

Florida is an admirable country for raising stock, and formerly the rearing of cattle and horses was the chief employment of the small planters. Deer are very abundant, and hunting is pursued to a considerable extent, although the Indians complain of the scarcity of game. Wolves sometimes assemble in great numbers, and, whether united or single, they are always formidable enemies to the folds and vacheries of the planters. Bears are still found here, and their flesh is esteemed a luxury by the inhabitants. The other quadrupeds of Florida are, wild cats, panthers, foxes, rabbits, many beautiful kinds of squirrels, raccoons, Mexican oppossums, and wood-cocks.

The ornithology of Florida is probably the richest in North America. The variety and splendour of the birds is one of the most striking features of the country. Those of the aquatic species are immensely numerous, especially during winter. In the woods are vultures, hawks, rooks, jays, parroquets, wood-peckers, pigeons, turkeys, herons, cranes, curlews, cormorants, plovers, blue birds, mocking-birds, red birds, and great varieties of the sparrow tribes. The dog-wood groves are the resort of vast numbers of the small singing birds. Among the remarkable specimens of the feathered tribes are the snake birds, a species of cormorant of great beauty. Wild ducks and wild geese are found in prodigious flights; wild turkeys are plentiful, and of a very large size.

The sea coasts, the rivers, and the lakes, abound with every variety of fish, and furnish food to the greater proportion of the people, especially on fast days and in Lent. The rivers and lakes swarm with alligators, who feed most voraciously on the innumerable fry of smaller fish. The abundance of these smaller fish is a most singular fact. The sea-shore abounds with sharks, which, like the alligators, find a supply of food by preying on the smaller tribes, which, when pursued by those voracious monsters, ascend the creeks to parts where they suddenly contract, and so fill the water as to impede the passage of a boat. In some instances, where the contraction of the stream is very sudden and very great, those smaller fish have been seen so closely crowded as to become a mass actually filling the channel, and even rising, wedged together, above the surface of the water.

Various kinds of serpents are common in Florida, and incredible numbers of the small insects called ephemeræ cover the surfaces of the lakes and rivers, supplying abundant food for the birds, frogs, and fishes. Gnats, mosquitos, and other insects, also abound, and in some parts are extremely annoying.

This country was, in some respects, an invaluable acquisition to the United States. Besides its political importance, it was necessary to them on account of its harbours, its immense line of coast, and its inexhaustible supplies of ship timber. From the period of the incorporation of Florida with the North American States, emigration to this state has been considerable. It has been divided into counties, judicial and military districts; and the benefits of American institutions have been diffused over its whole extent. The present number of inhabitants is estimated at about 35,000. They comprehend emigrants from all countries, and from every American state, and they are as thoroughly mixed as any community in the United States. Almost all the inhabitants are poor, and too great a proportion of the recent emigrants consists of mere adventurers. Most of the ancient inhabitants lead a pastoral life, and subsist by the rearing of cattle. A few of the planters are opulent, and possess good houses, which are generally situated in remote forests and savannahs. They are said to be remarkable for their hospitality to strangers.

Of the Indians, which were formerly so numerous and powerful in this country, only a few small fragments of tribes remain, which, with refugees from other tribes, are dispersed throughout the forests and savannahs. The Indians of this region are an alert, active, and athletic people; of joyous dispositions, and fond of war. They have the common propensity for intoxicating liquor, and for gambling. As hunters they are expert; and by the sale of bear, deer, panther, and wolf skins, of horses and cattle, bees' wax, honey, venison, and such articles as are the produce of the chase, they procure the necessaries of life.

The chief town of East Florida, and the most populous in the country, is St Augustine. It is situated on the Atlantic coast, thirty miles below the mouth of St Johns, on an inlet behind the island of St Anastasia, in north lat. 29. 45. It is about two miles within the bar, which has only from eight to ten feet of water, thus precluding the entrance of large vessels into the harbour. The town is built of an oblong form; it is surrounded by a ditch, fortified by bastions, and defended by a castle called Fort St John. The river St Mark flows through the harbour, and divides the town from the island. The streets are in general narrow; the houses are not more than two stories high, with thick walls, spacious entries, large doors, windows, and balconies, and having commonly a fine garden attached to them. Although the soil around St Augustine is so sandy as to have the appearance of being sterile, yet it is productive to a considerable extent. It yields two crops of maize yearly, and garden vegetables are reared in abundance. The orange and lemon arrive at great perfection here; the palm or date tree grows near to the town, and the olive has become naturalized in the soil. The population of St Augustine consists of between 4000 and 5000 inhabitants. The capital of West Florida is Pensacola, which is situated on a bay of the same name, in long. 87. 12. W. and lat. 30. 20. N. The shore is low and sandy, but the town is built on a gentle ascent. Like St Augustine, it is of an oblong form, and nearly a mile in length. Small vessels only can come close up to the town; but the bay affords one of the safest and most capacious places of shelter for shipping in the Gulf of Mexico. This town has been selected by the American government as a naval station and depôt, for which it is admirably adapted. Pensacola has increased in prosperity since its union with the United States, and at present contains about 3000 inhabitants.

The seat of government for the territory of Florida is Tallahasse. The position of this town was fixed upon in 1824, and in the year following it was divided into lots, and immediately incorporated as a city. The situation of Tallahasse is remarkably pleasant, and is supposed to be healthy. The ground on which it stands is considerably elevated, and the surrounding country is high. An elevated chain of hills bounds the shores of the Mexican Gulf, and the town lies three miles north of this ridge, in long. 84. 36. W. and lat. 30. 28. N. The country around is generally fertile, and suited to the cultivation of sugar. At present it is covered with various kinds of trees, amongst which is an excellent kind of mahogany. In 1830 the population amounted to about 1200. St Marks, an inconsiderable place, situated at the distance of nine miles from Tallahasse, is the nearest sea-port. The other towns, villages, &c. of this territory are too insignificant to require a separate description.

It is contemplated to cut a canal through Florida, which, when accomplished, will develope its resources, and cause the country to present many attractions to the emigrant. Upon this subject Mr Flint observes, "As an agricultural country, it must be confessed, a great part of Florida is sterile. The level pine forest lands will bring one or two crops of corn without manure; and will probably be cultivated to a certain extent with indigo. The drier lands of this sort are admirable for sweet potatoes, and on the whole better, with the requisite cultivation and manuring, for gardens, than soils naturally more fertile. There are considerable bodies of excellent land distributed at wide intervals over all the country; but a small proportion of these are what are denominated first rate. Some parts, probably, offer equal advantages for the cultivation of sugar with the sugar lands of Louisiana. Cochineal, it is supposed, will be made to advantage, and, it may be, coffee. It offers superior maritime advantages of every sort; abounds in the materials of ship-building; and, in its rich and inexhaustible fisheries, and its supply of oysters and sea fowl, has its own peculiar advantages. The immigrant, who sought to enrich himself by cultivation alone would probably make his way to the richer soils west of the Mississippi. But, if taken as a whole, it is more sterile than the country along the Mississippi, it feels the refreshing coolness of the sea breeze and the trade winds, and it is beyond a doubt more healthy."

The counties and chief towns, besides those already mentioned, are, Alachua, *Dell;* Duval, *Jacksonville;* Escambia, *Pensacola;* Hamilton, *Miccotown;* Jackson, *Marianna;* Jefferson, *Monticello;* Leon, *Tallahasse*, 896 miles from Washington; Madison, *Hickstown;* Monro, *Key West;* Moscheto, *Tomoka;* Nassau, *Ferdinanda;* St Johns, *St Augustine*, 841 miles from Washington, 292 south-east from Tallahasse; Walton, *Aliqua;* Washington, *Holme's Valley*. There are also Gadsden, Fayette, and some other new counties.

FLORILEGIUM, FLORILEGE, a name given by the Latins to what the Greeks call *ανθολογιον*, *anthology*, a collection of choice pieces, containing the finest and brightest things of their kind.

FLORILEGE is also particularly used for a kind of breviary, in the Eastern church, compiled by Arcadius, for the convenience of the Greek priests and monks. The florilegium contains the general rubrics, psalter, canticles, the horologium, and the office of the feriæ.

FLORIN is sometimes used to signify a coin, and sometimes a money of account. Florin, as a coin, is of different values, according to the different metals, and different countries where it is struck. See MONEY.

FLORINIANI, or FLORIANI, a sect of heretics of the second century, so denominated from its author Florinus, or Florianus, a priest of the Roman Catholic church, deposed along with Blastus for his errors. Florinus had, along with Irenæus, been a disciple of St Polycarp. He made God the author of evil; or rather asserted that the things forbidden by God are not evil, but of his own appointment. The Floriani had also other names given them. Philastrius says they were the same with the *Carpophorians;* and they were also called soldiers, *milites quia de militaribus fuerunt*. St Irenæus calls them *Gnostics;* St Epiphanius, *Phibionites;* and Theodoret, *Barbarites*, on account of the impurities of their lives; whilst others call them *Zaccheans*, and *Coddians*.

FLORIS, FRANCIS, an eminent historical painter, was born at Antwerp in 1520. He followed the profession of a statuary till he was twenty years of age, when, preferring painting to sculpture, he entered the school of Lambert Lombard, and afterwards went to Italy, where he completed his studies. The great progress he made procured him much employment on his return, and his countrymen complimented him with the appellation of *the Flemish Raffaelle.* He died in 1570, aged fifty.

FLORIST, a person curious or skilled in flowers, their kinds, names, characters, and culture. It is also applied to an author who writes what is called the flora of any particular place, that is, a catalogue of the plants and trees which are found spontaneously growing there.

FLORUS, LUCIUS ANNÆUS, a Latin historian. Respecting the time when he flourished, and the country from which he sprung, we have no certain information. Some have supposed him to be of Spanish origin, connected with the family of Seneca; others have imagined that he came from Gaul. It has been suggested that he may be the same with Julius Florus Secundus, celebrated by Quintilian for his eloquence; whilst others have ascribed the work which we possess under his name to Lucius Annæus Seneca. But be this as it may, there seems good reason for believing that he lived under Hadrian or Trajan. The work left by him entitled *Epitome de Gestis Romanorum*, in four books, is a summary of Roman history from the building of the city to 29 B. C. (725 U. C.), when Augustus closed the temple of Janus. He does not seem to have followed Livy entirely in his narrative, but to have had recourse to older historians. It can scarcely however be considered as a history; it is rather a panegyric pronounced on the whole conduct of the Roman people, written with great elegance of language, and imbued with a rhetorical spirit. The treatment of the subject is poetical, and far removed from the severe dignity of history. In the language, we have sometimes cause to regret the purity of the Augustan age; but in other respects the style is flowing and eloquent, rising far above the age in which the author must have flourished. The short arguments prefixed to the books of Livy are also ascribed to Florus. The best editions of his work are that of Grævius, *Traject. ad Rhen.* 1680; Leipsic, 1760; Bipont, 1754; Titze, 1819; Amer. Par. 1822. See Titze, *de Flori Ætate*, Linz. 1804.

FLORY, FLOWERY, or FLEURY, in *Heraldry*, a cross which has flowers at the end circumflex and turning down, and which is different from the *potence*, in as much as the latter stretches out more like that which is called *patée*.

FLOTSON, or FLOTSOM. Goods which by shipwreck are lost, and floating upon the sea, are, with jetsom and ligan, generally given to the lord admiral. But this is the case only where the owners of such goods are not known. It is also to be observed that *jetsom* signifies any thing which is cast out of a ship when in danger, and afterwards beat on the shore by the water, notwithstanding which the ship perishes. *Ligan* is where heavy goods are thrown overboard, before the wreck of the ship, and sink to the bottom of the sea.

FLOUNDER, FLUKE, or BUT. See ICHTHYOLOGY.

FLOUR, the meal of wheat-corn, finely ground and sifted.

FLOUR, ST, an arrondissement of the department of Cantal, in France, extending over 660 square miles. It is divided into six cantons and eighty-two communes, and contains 65,079 inhabitants. The capital is a city built on a hill of basalt, 300 feet high, and only accessible on one side, at the foot of which flows the river Dauzan. The streets are paved, and the houses constructed of basalt, which gives the whole a gloomy appearance, and hence the neighbours have named it the black city. It contains 800 houses, and

5687 inhabitants, who are occupied in manufactures of glass, leather, copper, and iron goods, and archil. Long. 3. 0. 19. E. Lat. 45. 1. 58. N.

FLOWER (*Flos*), among botanists and gardeners, the most beautiful part of trees and plants, containing the organs or parts of fructification. Flowers were in great request at the entertainments of the ancients, being provided by the master of the feast, and brought in before the second course; or, as some think, at the beginning of the entertainment.

Preserving of F*lowers*. The method of preserving flowers in their natural beauty throughout the whole year has been much sought after by many. Some have attempted it by gathering them when dry and not too much opened, and burying them in sand; but this, though it preserves their figure well, diminishes the liveliness of their colour. Muntingius prefers the following method: Gather roses, or other flowers, when they are not yet thoroughly open, in the middle of a dry day; fill the vessel with them up to the top, and when full sprinkle them over with some good French wine, with a little salt in it; then set them by in a cellar, tying down the mouth of the pot. After this they may be taken out at pleasure; and, on placing them in the sun, or within reach of the fire, they will open as if growing naturally; and not only will the colour, but the smell also, be preserved.

The flowers of plants are by much the most difficult parts of them to preserve in any tolerable degree of perfection. Of this we have instances in all the collections of dried plants, or *horti sicci*. In these the leaves, stalks, roots, and seeds of the plants, appear very well preserved; the strong texture of such parts making them always retain their natural form, and the colours in many species naturally remaining. But it is very much otherwise in regard to flowers, which are naturally the most beautiful parts of the plants to which they belong; they are however so much injured in the common way of drying, that they not only lose, but change their colours, by which means occasion is given to many errors; and they usually also wither up, so as to lose their very form and natural shape. The primrose and cowslip kinds are instances of the change of colours in the flowers of dried specimens; for those of this class of plants easily dry in their natural state, but they lose their yellow, and, instead of it, acquire a fine green colour, much superior to that of the leaves in their most perfect state. The flowers of all the violet kind lose their beautiful blue, and become of a dead white; so that in dried specimens there is no difference between the blue-flowered violet and the white-flowered kinds.

Sir Robert Southwell has communicated to the world a method of drying plants, by which this defect is proposed to be in a great measure remedied, and all flowers preserved in their natural shape, and many in their natural colours. For this purpose two plates of iron are prepared of the size of a large half sheet of paper, or larger, for particular occasions. These plates should be made so thick as not to be apt to bend; and there must be a hole made near every corner for receiving a screw to fasten them closely together. When the plates are prepared, have in readiness several sheets of paper, and then gather the plants with their flowers when they are quite perfect. Let this be always done in the middle of a dry day; and then place the plant and its flower on one of the sheets of paper doubled in half, spreading out all the leaves and petals as nicely as possible. If the stalk be thick, it must be pared or cut in two, so that it may lie flat; and if it be woody, it may be peeled, and only the bark left. When the plant is thus expanded, lay round about it some loose leaves and petals of the flower, which may serve to complete any part that is deficient. When all is thus prepared, lay several sheets of paper over the plant, and as many under it; then put the whole between the iron plates, laying the papers smoothly on one, and placing the other equally over them; screw them close, put them into an oven after the bread is drawn, and let them lie there two hours. After this, make a mixture of equal parts of aquafortis and common brandy; shake these well together, and when the flowers are taken out of the pressure of the plates, rub them lightly over with a camel's hair pencil dipped in this liquor; then lay them upon fresh brown paper, and covering them with some other sheets, press them between this and other papers with a handkerchief till the moisture of these liquors is wholly dried away. When the plant is thus far prepared, take the bulk of a nutmeg of gum-dragon, put this into a pint of pure cold water, and let it stand twenty-four hours, in which time it will be wholly dissolved; then dip a fine hair pencil in this liquor, and with it daub over the posterior sides of the leaves, and lay them carefully down on half a sheet of white paper fairly expanded, and press them down with some more papers over these. When the gum water is fixed, let the pressure and paper be removed, and the whole work is finished. The leaves in this case retain their verdure, and the flowers usually preserve their natural colours. Some care, however, must be taken that the heat of the oven be not too great. When the flowers are thick and bulky, some art should be used to pair off their backs, and dispose the petals in a due order; after which, if any of them are wanting, their places may be supplied with some of the supernumerary ones dried on purpose; and if any of them are only faded, it will be prudent to take them away, and lay down others in their stead. The leaves may be also disposed and mended in the same manner.

Another method of preserving both flowers and fruits throughout the whole year is also given by the same author. Take saltpetre one pound, Armenian bole two pounds, clean common sand three pounds, and mix the whole well together. Then gather fruit of any kind that is not fully ripe, with the stalk to each; and put in these, one by one, into a wide-mouthed glass, laying them in good order. Tie over the top with an oil-cloth, carry them into a dry cellar, and set the whole upon a bed of the prepared matter of four inches thick in a box. Fill up the remainder of the box with the same preparation, and let it be four inches thick all over the top of the glass and all round its sides. Flowers are to be preserved in the same sort of glasses, and in the same manner; and they may be taken up after a whole year as plump and fair as when they were buried.

FLUDD, Robert (called in Latin De Fluctibus), a person of some celebrity in his time, was the son of Sir Thomas Fludd, treasurer of war to Queen Elizabeth in France and the Low Countries, and was born at Milgate, Kent, in the year 1574. He received his education at St John's College, Oxford, and afterwards spent six years in travelling through France, Spain, Italy, and Germany. He acquired a strong attachment to the Rosicrucian philosophy, which consisted chiefly of a mystic or cabbalistical jargon, and those who were initiated therein had certain secrets communicated to them analogous to those of freemasonry. On his return home Fludd took the degree of doctor of medicine, settled in the city of London, and became a fellow of the College of Physicians. His piety was of an enthusiastic kind, and the seeming depth of his knowledge gained him much admiration, and procured him temporary celebrity. It is said that he employed a kind of unintelligible cant when speaking to his patients, which sometimes contributed to their recovery, as it operated on their faith, and through it on the imagination. But he is chiefly known as an adept in philosophy, not as a physician. Blending the incomprehensible reveries of the Cabbalists and Paracelsians, he formed a new physical system, replete with mystery and absurdity, and believed in two universal principles, the northern or condensing, and the southern or rarefying power. Innumerable genii, as he conceived, presided over these powers, and committed the charge of diseases to legions of spirits collected from the four winds of heaven. In his estimation, a harmony subsisted between the macrocosm and the microcosm, or the world of nature and the world of man. It is impossible to enumerate all his fancies and whims, which, however absurd and extravagant, being supported by mysterious gravity and the semblance of erudition, attracted the notice of the philosophers of that age. Even Kepler himself thought the preposterous jargon of Fludd worthy of refutation, and Gassendi with the same view wrote his *Examen Philosophiæ Fluddianæ*, 1629. Fludd wrote two books against Mersenne, the first entitled *Sophiæ cum Moria certamen, in quo lapis Lydius, a falso structore Patre Marino Mersenno monacho reprobatus, celeberrima voluminis sui Babylonici in Genesim figmenta accurate examinat*, Francfort, 1629, folio; and the second, *Summum Bonorum, quod est verum Magiæ, Cabalæ, Alchymiæ, Fratrum Roseæ Crucis Verorum, Subjectum*, etc. 1629, folio. His other works were, 1. *Utriusque Cosmi, majoris et minoris, Technica Historia*, Appenheim, 1617, in 2 vols. folio; 2. *Tractatus Apologeticus integritatem Soc. de Rosea Cruce defendens*, Leyden, 1617; 3. *Monochordon Mundi symphoniacum, seu Replicatio ad Apologiam Joannis Kepleri*, Francfort, 1620; 4. *Anatomiæ Theatrum triplici effigie designatum*, ibid. 1623; 5. *Philosophia Sacra et vere Christiana, seu Meteorologia Cosmica*, ibid. 1626; 6. *Medicina Catholica, seu mysticum artis medicandi sacrarium*, ibid. 1626; 7. *Integrum Morborum mysterium*, ibid. 1631; 8. *De Morborum Signis*, ibid. 1631; 9. *Clavis Philosophiæ et Alchymiæ Fluddianæ*, ibid. 1633; 10. *Philosophia Mosaica*, Goudæ, 1638; and, 11. *Pathologia Dæmoniaca*, ibid. 1640.

FLUENT, or Flowing Quantity. See Fluxions.

FLUID, an appellation given to all bodies, the particles of which easily yield to the least pressure or force impressed. See Hydrodynamics.

FLUTE, an instrument of music, the simplest of all those of the wind kind. It is played on by blowing it with the mouth; and the tones or notes are changed by stopping and opening the ventiges arranged along its side. There is a very ancient instrument. It was at first called the flute *a bec*, from *bec*, an old Gaulish word signifying the beak of a bird or fowl, but more especially of a cock; the term *flute a bec* therefore signifies the *beaked flute*, which appears a very proper appellation in comparison with the traverse or German flute. The word *flute* is derived from *fluta*, the Latin for a lamprey or small eel found in the Sicilian Seas, and having seven holes immediately below the gills on each side, the precise number of those in the front of the flute.

By Mersenne this instrument is called the *fistula dulcis seu Anglica;* and, according to him, the lowest note for the treble flute is *C fa ut*, and the compass of the instrument fifteen notes. There is however a flute known by the name of the *concert flute*, the lowest note of which is F. Indeed ever since the introduction of the flute into concerts, the lowest note of the instrument, of what size soever it may be, has been called F; when in truth its pitch is determinable only by its correspondence in respect of acuteness or gravity with one or other of the chords in the *scala maxima* or great system.

Besides the true concert flute, others of a less size were soon introduced into concerts of violins; in which case the method was to write the flute part in a key corresponding to its pitch. This practice was introduced in 1710 by one Woodcock, a celebrated performer on this instrument, and William Babell, organist of the church of All-Hallows, Bread Street, London. They failed, however, in procuring for the flute a reception into concerts of various instruments; for which reason Thomas Stanesby, a curious maker of flutes and other instruments of the like kind, having about the year 1732 adverted to the scale of Mersenne, in which the lowest note is C, invented what he called the *new system*, in which, by making the flute of such a size as to be a fifth above concert pitch, the lowest note became *C sol fa ut*. By this contrivance the necessity of transposing the flute part was taken away; for a flute of this size, adjusted to the system above mentioned, became an octave to the violin. To further this invention of Stanesby's, Louis Merci, performer on the flute, published, about the year 1735, six solos for this instrument, three of which are said to be accommodated to Stanesby's new system; but the German flute had now become a favourite instrument, and Stanesby's ingenuity failed to produce the effect intended. Indeed one great objection against this instrument, which equally affects all perforated pipes, is, that they are never perfectly in tune, or cannot be made to play all their notes with equal exactness. The utmost that the makers of them can do is to tune them to some one key; and to effect this truly, is a matter of no small difficulty. The English flutes made by the younger Stanesby came the nearest to perfection; but those of Bressan, though excellent in their tone, were all too flat in the upper octave. For these reasons some are induced to think that the utmost degree of proficiency on any of those instruments is not worth the labour of attaining it.

German Flute is an instrument entirely different from the common flute. It is not, like the latter, put into the mouth to be played; but the end is stopt with a tompion or plug, and the lower lip is applied to a hole about two inches and a half or three inches distant from the end. This instrument is usually about a foot and a half in length; rather larger at the upper end than the lower; and perforated with holes, besides that for the mouth, the lowest of which is stopped and opened by the little finger pressing on a brass or sometimes a silver key, like those in hautboys, bassoons, and other similar instruments. Its sound is exceedingly sweet and agreeable; and it serves as a treble in a concert.

Flute, or Fluyt, is a kind of long vessel, with flat ribs or floor timbers, round aft, and swelled in the middle, which serves chiefly for carrying provisions in fleets or squadrons of ships, though it is often used in merchandise. The word *flute*, signifying a sort of boat or vessel, is, according to Borel, derived from the ancient *flotte*, a little boat. In the verbal process of the miracles of St Catherine of Sweden, in the twelfth century, we meet with the following words: "Unus equum suum una cum mercibus magni ponderis introduxit super instrumentum de lignis fabricatum, vulgariter dictum *fluta*."

FLUX, in *Medicine*, an extraordinary issue or evacuation of some humour. Fluxes are of different kinds and variously denominated, according to their seats or the humours thus voided; as a flux of the belly, uterine flux, hepatic flux, salival flux, and the like. See Medicine.

Flux, in *Hydrography*, a regular periodical motion of the sea, happening twice in twenty-four hours, in which the water is raised and driven violently against the shores. The flux or flow is one of the motions of the tide; the other, by which the water sinks and retires, is called the reflux or ebb. There is also a kind of rest or cessation of about half an hour between the flux and reflux, during which time the water is at its greatest height, and thence called *high water*. See Tides.

FLUXIONS.

INTRODUCTION.

The calculus of fluxions, the most important addition that ever was made to the fabric of abstract science, was invented in the latter part of the seventeenth century. Considered as a purely intellectual speculation, it far transcends any theory that had been previously known in pure mathematics; and it is not less estimable by reason of its applicability to physical knowledge. By its powers as an instrument of analysis, the science of geometry has been exceedingly enlarged; and the elegant speculations of the ancient geometers now go but a little way into the vast field of knowledge which has been laid open by the fluxional calculus, the sublime discoveries of Apollonius and Archimedes being merely easy deductions from more extended theories. It has, further, rendered most efficient aid in the investigation of the laws of nature, more especially in establishing the true theory of the motions of the heavenly bodies, which, without its assistance, could not have attained its present high position in the scale of human knowledge.

It may easily be supposed that the invention of the calculus was not at once fully revealed to the world. Its principles being inherent in the nature of geometrical magnitude, they would of course be gradually disclosed with the advance of mathematical science.

As long as the geometers of antiquity confined their speculations to the comparison of figures bounded by straight lines, there was no difficulty. The axioms and the mental process of conceiving the magnitudes compared to be placed one upon another, was sufficient to establish the equality of triangles in the cases when these could be brought entirely to coincide. The principle of superposition might have been carried further in the elements, so as to prove the equality of parallelograms, which are the complements of those about the diameter of a parallelogram; also of parallelograms having equal bases and altitudes; and the equality of the square on the hypotenuse of a right angled triangle to the squares on its sides. In fact, the doctrines of plane geometry were sufficient to prove that any two equal rectilineal figures admit always of being decomposed into spaces, such that, corresponding to every space in one of the figures, there may be found a space exactly equal and similar to it in the other figure; so that in this way any two equal rectilineal figures, however dissimilar, may yet, by division, be brought to coincide.

The principle of superposition, which was sufficient for the comparison of rectilineal plane figures, one with another, could not, however, be extended to the comparison of rectilineal with curvilineal, or of curvilineal with curvilineal figures. In treating of these, the ancients found it necessary to introduce new notions and modes of demonstration into geometry; and the difficulty which occurred in reasoning about curvilineal figures gave rise to the method of exhaustions, the most refined and important of their geometrical theories.

The fundamental principle of the method of exhaustions is this very simple proposition, that the difference of any two unequal quantities, by which the greater exceeds the less, may be added to itself so often, as to exceed any finite quantity of the same kind. On this the geometers of antiquity founded their propositions concerning curvilineal figures. By its aid they found that polygons may be inscribed in circles, which shall differ from them by less than any assignable space; and hence they might infer that the circles have to each other the same ratio as similar polygons inscribed in them, namely, the squares of their diameters. Although in this way they could assure themselves of the truth of the propositions, yet as this kind of proof was of a looser nature than that by which they established their more elementary doctrines, they fortified it against all cavil by their usual mode of synthetic demonstration, proving that the square of the diameter of one circle was to that of another as the first circle to a space that was neither less nor greater than the second, and therefore exactly equal to it. By a like process they proved that a cone is one third of a cylinder of the same base and altitude; and from the demonstrations which they gave of these propositions, it might be concluded in general, that when two variable quantities which have a constant ratio approach to two determined quantities, so as to differ at last from them by less than any assignable space, the same constant ratio is also the ratio of the determined quantities, which are the limits of the variable quantities.

Introduction.

The cautious way in which the ancients proceeded in finally establishing the truth of their propositions concerning the proportions of solids, could be of very little use in their original discovery. Indeed we may reasonably suppose, that in the first instance they arrived at a knowledge of their truth by a much shorter road, probably in a way not very different from that followed by the earlier geometers in modern times, who have extended their theories. But whatever path they followed, it led them to some truths of the highest importance at the time they were first known. After ages of fruitless labour in attempting to square the circle, the fine discoveries of Archimedes, that the parabola was two thirds of its circumscribing parallelogram, and the sphere two thirds of its circumscribing cylinder, and its surface four times that of one of its great circles, must have been received by his contemporaries with high satisfaction.

In the beginning of the seventeenth century, the writings of Archimedes greatly engaged the attention of the principal cultivators of mathematical science, who soon seized the spirit of his method, which was altogether distinct from the unwieldy machinery of the ancient mode of synthetic demonstration. He had only considered such solids as could be generated by the revolution of conic sections about an axis, and he had not even exhausted all the cases of these. The celebrated Kepler greatly extended this theory, in a treatise which he composed on the mensuration of round solids. These he conceived to be formed by the revolution of the conic sections about any ordinate, or a tangent to the curve at the vertex, or, in short, about any line whatever within or without the curve. In this way he described about ninety new solids, and proposed them as problems for the consideration of his contemporaries; but of these he resolved only a few of the most simple. In this work he first introduced the name and notion of infinity into the language of geometry. He considered the circle as composed of an infinite number of triangles, having their vertex at the centre, and forming the circumference by their bases. The cone he regarded as composed of an infinite number of pyramids, resting on the infinitely small triangles which formed its circular base, and having their vertices at its vertex; and he supposed a cylinder of the same base and altitude as the cone to be made up of prisms having the same bases and altitudes as those which composed the cone.

The bold extension which Kepler thus gave to the cautious language of geometry drew the attention of his contemporaries, some of whom eagerly followed in his steps. Cavalieri, a friend and disciple of Galileo, embodied the new views in his geometry of indivisibles, the theory of which he possessed in 1629, although it was not published until 1635. In this work, lines were considered as made up of points, surfaces as composed of lines, and solids as formed of surfaces. Cavalieri was exceedingly careful to verify his method, comparing his results with those which had been established by the ancient geometrical mode of demonstration; and, assured by their agreement, he ventured boldly in his new career. His principles were attacked, but he defended them by showing that they might be translated into those of Archimedes, from which they only differed in brevity of expression; his surfaces and lines being in fact merely the thin solids and small inscribed and circumscribed triangles of the ancient geometer, and their number being supposed so great that the difference between them and the figure about which they were described was less than any assignable quantity.

The new views proposed by Kepler were taken up in France by Roberval, who had carefully studied the writings of Archimedes, and formed a theory by which he could resolve problems concerning curvilineal figures. Instead of supposing lines to be made up of points, and surfaces of lines, as had been assumed by Cavalieri, he regarded a line as composed of an infinite number of infinitely short lines, a surface as composed of an infinite number of infinitely narrow surfaces, and so on; an assumption which at bottom was the same as that of the Italian geometer, but capable of being wrought up into a theory differing less from the spirit of the ancient geometry. Roberval concealed his views, employing them secretly as the means of invention in geometry, and expecting in this way to get the start of his contemporaries in reputation as a geometer. In the meanwhile the work of Cavalieri appeared and frustrated his selfish expectations.

The facility which the introduction of the notion of infinitely small quantities gave in the extension of geometry, induced all the mathematicians of that day to employ it in their researches. In the doctrine of curve lines it was applied to the theory of tangents by Roberval, Descartes, and Fermat, with great success. So very near had this last-mentioned geometer approached to the fluxional or differential calculus, that Laplace says he ought to be reputed its true inventor. Laplace was no doubt a great authority; but the facts on which he formed his opinion have always been generally known, and no one before him has attempted to reverse the decision of the age in which the calculus was invented. The justice of the decision has been subjected to a scrutiny by men of the highest powers of mind, who, differing in many of their opinions, have yet agreed in ascribing the invention to others.

The problem of drawing tangents to curves is indeed closely connected with the calculus, and at the period when this was about to be revealed that problem was much agitated, and successfully resolved by Slusius, Wallis, Barrow, and others. The writings and discoveries of Descartes exerted a most beneficial influence on the new geometry, particularly by his happy application of algebra to geometry. Before his time geometrical problems had been resolved by algebra, and a rich mine of discovery thereby opened. But he was the first who thought of applying algebraic formulæ to express the nature of curve lines; an invention of vast importance to both branches of mathematical science.

Another most important benefit that resulted from the new views which Descartes brought forward, was the notion of *variable quantity*. The early analysts distinguished quantities chiefly from the circumstance of their being known or unknown; and the main object of inquiry with them was to discover the chain of reasoning by which they might pass from the given quantities to the determination of those required. The view which Descartes took of geometrical magnitude brought the *relations* of quantities forward as a principal subject of contemplation. A new subject of discussion was brought into mathematical science, namely, the changes which take place in quantities connected by an invariable relation, when one of them is supposed to change its value, and pass from one state of magnitude to another. The science of geometry owes its elegance and the variety of its doctrines to the combined effect of magnitude and position, as they influence the subjects under consideration; and, in addition to these, the doctrine of curve lines has introduced a new element, namely, the property of varying in magnitude, as an attribute of quantity. This property of indefinitude, in respect of greatness, although it may appear a trivial affection of quantity, has, however, led to the most important consequences; for from this, combined with other principles, have sprung the fluxional calculus and other mathematical theories, which, originating in the ordinary conceptions of the human mind, have engaged the attention of men endowed with the highest powers of intellect for more than a century past.

In the progress of time the notions of infinite quantity introduced by Kepler, Cavalieri, and others, into mathematics, became familiar to geometers, who perceived the immense value of the improvement, and saw that, by due care in its application, there was no risk of its leading into error. Dr Wallis, in the year 1655, gave an admirable specimen of this new analysis in his *Arithmetic of Infinites*; a work which contained the first traces of the algebraic analysis applied to the quadrature of curvilineal spaces. Pursuing the views of Cavalieri, he reduced the problem of finding the areas of curves to the summation of the powers of an arithmetical series, consisting of an infinite number of terms, or rather the ratio of the mean of all the terms to the last term. He also showed by the same principles, that certain curve lines might be *rectified*, or that straight lines might be found to which they were exactly equal; a remark that was shortly afterwards verified by William Neil, a young mathematician of that period, who, at the age of nineteen, showed that the length of the semicubical parabola might be found in finite terms. This was the first curve that was rectified, and the second was the cycloid, a discovery due to Sir Christopher Wren.

Thus the principles of the fluxional calculus were at this period coming gradually into view. Their importance was seen and understood, and in substance, although without an appropriate notation, they were employed in extending the dominion of geometry; it might therefore be supposed that in the course of time they would have been gradually formed into a system, just in the way the science of algebra advanced from the rude form it had when first introduced into Italy, to that degree of compactness and perfection which it acquired by the successive improvements of Vieta, Harriot, and Descartes. But, in the case of the fluxional calculus, a happy combination of circumstances anticipated the slow operation of time. Newton and Leibnitz, two men endowed with the highest powers of mind, appeared nearly at the same time in the field of discovery. The genius of each shone with resplendent lustre, even amidst the blaze of intellect which enlightened the latter period of the seventeenth century, and which has rendered it for ever memorable in the annals of hu-

Introduction.

man knowledge. They both turned their attention to this branch of mathematical science, and, as is now generally admitted, each, independently of the other, collected the undigested principles into a system, and, by a powerful effort, performed at once what the united labour of ordinary minds would have hardly accomplished in a century.

In ascribing to each of these great men the full honour due to the merit of the invention of the calculus, it is proper to add, that this is a question which at one time divided the opinions of the learned world, and gave rise to a controversy which was agitated with great keenness for almost a whole century. There never could be any doubt as to Newton being the inventor of the calculus of fluxions. He has been acknowledged by all to have been the inventor, and the first inventor; but the question strongly contested has been, whether Leibnitz, without knowing what had been done by Newton, invented his differential calculus by the force of his own mind, or borrowed it from the fluxional calculus, with which at bottom it is identical.

In the course of this controversy it was clearly established by the British mathematicians, who almost to a man ranged themselves on the side of their illustrious countryman, that, as far back as the year 1669, Newton, then in his twenty-sixth year, and a fellow of Trinity College, communicated to Dr Barrow a tract, entitled *De Analysi per Æquationes Numero Terminorum Infinitas.* In this manuscript the method of fluxions was first indicated; and rules deduced from it given for the quadrature of curves, and various other matters to which the calculus is applicable, were distinctly specified. From this tract, which was sent by Dr Barrow to Collins, the secretary of the Royal Society, it is established beyond all doubt that Newton was then in full possession of his method; and indeed it is certain from other evidence that he must have had it as far back as 1666. The important discoveries made by Newton were communicated without reserve by the secretaries of the Royal Society to mathematicians on the Continent, as well as to those in Britain. In this way it might be generally known that Newton possessed a most valuable instrument of research, by which he had been led to these results, although its nature was too obscurely indicated to give any assistance in divining its precise form.

Leibnitz appears to have been later than Newton in beginning his career of discovery in the mathematics. In the year 1672, being then in London, he communicated to some members of the Royal Society what he supposed to be discoveries relating to the differences of numbers. It was, however, shown to him that the same subject had been discussed long before, by Mouton, a French geometer. He then appears for the first time to have turned his attention to infinite series. Afterwards, on his return to Germany in 1674, he announced to Mr Oldenburgh, then secretary of the Royal Society of London, that he possessed very general analytical methods, by which he had found theorems of great importance relating to the quadrature of the circle, by means of series. In answer, the secretary informed him that Newton and James Gregory had also discovered methods which gave the quadrature of curves, and which extended to the circle.

In the year 1676 Newton addressed a letter to the secretary of the Royal Society, which was made known to Leibnitz. This was the first direct communication between these two great men. It contained the binomial theorem, which Newton had known in the year 1669, and a variety of other matters relating to infinite series and quadratures; but nothing directly relating to the method of fluxions. At this time Newton entertained no jealousy of Leibnitz, for he speaks of him in the letter with great respect. In a second letter Newton explained at his request the way in which he had found the binomial theorem, and he adverted also to his own calculus, explaining the purposes to which it could be applied, but concealing its nature under the form of an anagram of transposed letters, which was expressed thus, *6accdae13eff713l9n4o49rr4s9t12vx.* It is not easy to see what certain information Leibnitz could draw from this assemblage of characters; yet such was the effect of national prejudice in biassing the minds of the British mathematicians, that Raphson, in his *History of Fluxions*, a work dedicated to the Royal Society of London, expressly asserts that Leibnitz deciphered the anagram, and found it to be this sentence, *Data equatione fluentes quotcunque quantitates involvente invenire fluxiones, et vice versa.* "Having any given equation involving never so many flowing quantities, to find the fluxions, and *vice versa.*" We believe there was not the least ground for this assertion; and from such a specimen of want of candour, it is easy to infer that there was very little chance of Leibnitz getting justice done him by the English mathematicians.

In the month of June 1677 Leibnitz sent to Mr Oldenburgh, to be communicated to Newton, a letter containing the first essays of a method which extended to all that could be done by that of Newton. The death of Oldenburgh, which happened soon afterwards, put an end to the correspondence, and it was not until the year 1684 that Leibnitz made his discovery public, it being then inserted in the Leipsic Acts; so that whilst Newton's claim to the priority of the discovery must be admitted by all, it is not less certain that Leibnitz was the first to give the full benefit of the calculus to the world; for Newton's Method of Fluxions only became generally known in the year 1687, by the publication of his *Philosophiæ Naturalis Principia.*

It is certain that Leibnitz enjoyed unchallenged for fifteen years the honour of being the inventor of his calculus; even Newton himself rendered him that justice in the first edition of his immortal work. Subsequently, however, a foreign mathematician, Fatio de Duillier, piqued, it is said, by having been omitted in an enumeration of eminent geometers by Leibnitz, declared, in a treatise on the line of shortest descent, printed at London in 1699, that he was obliged by the undeniable evidence of things to acknowledge Newton not only as the first, but as by many years the first inventor of this calculus; from whom, whether Leibnitz, the second inventor, borrowed any thing or not, he would rather they who had seen Newton's letters and other manuscripts should judge than himself.

The insinuation contained in this passage of Fatio's book could not but be very offensive to Leibnitz, who inserted an animated reply in the Leipsic Acts of 1700, and complained to the Royal Society of London of the injustice done him; and here the affair rested for a time: but it was revived some years afterwards. When Newton's treatise on the quadrature of curves, and his enumeration of lines of the third order, was published, the Leipsic journalists gave an unfavourable review of the work. Amongst other things, after a brief exposition of the nature of fluxions, they added, that Newton uses and has always used fluxions for the differences of Leibnitz, just as Fabri had substituted in his synopsis of geometry motion instead of the indivisibles of Cavalieri. This most unjust accusation excited great indignation in the minds of the British mathematicians, one of whom, Keill, Savilian professor of astronomy at Oxford, in a paper inserted in the *Philosophical Transactions* of the year 1708, affirmed that Newton was the first inventor of the calculus, and that Leibnitz, in publishing it in the Leipsic Acts, had merely changed the name and the notation. Leibnitz, thus directly charg-

Introduction.

ed with having taken his calculus from that of Newton, addressed a letter to Mr, afterwards Sir Hans Sloane, the secretary of the Royal Society, in which he required that Keill should retract his accusation. Keill however refused to do this, and in answer addressed a letter to the secretary, in which he professed to show, not only that Newton had preceded Leibnitz in the invention, but that he had given so many indications of his calculus that its nature might easily be understood by any man of ordinary understanding. This letter was sent to Leibnitz, who addressed a second letter to the Royal Society, requiring that they should stop these reproaches of Keill, saying that he was too young a man to know what had passed between him and Newton.

The society, thus appealed to as a judge, appointed a committee to examine the old letters, papers, and documents which had passed between the mathematicians on the subject. The report of this committee does not appear altogether satisfactory. "We take the proper question to be," say the reporters, "not who invented this or that method, but who was the first inventor of the method; and we believe those who have reputed Leibnitz the first inventor, knew little or nothing of the correspondence between Mr Collins and Mr Oldenburg long before, nor of Mr Newton having that method about fifteen years before Mr Leibnitz began to publish his in the *Acta Eruditorum* of Leipsic; for which reason we reckon Mr Newton the first inventor, and are of opinion that Mr Keill, in asserting the same, has been nowise injurious to Mr Leibnitz." This declares nothing on the only point about which there could be any doubt, namely, whether Leibnitz had formed his calculus entirely by the power of his own genius, or had availed himself of a knowledge of Newton's invention. The judgment satisfied neither party. Keill wished to establish against Leibnitz the charge of plagiarism, but was disappointed; and Leibnitz found in the decision grounds of complaint against the Royal Society. In a communication to the Abbé Conti, a Venetian nobleman and a common friend of his and Newton, then in England, he accused the English nation of desiring to be considered as almost the only inventors. He said it did not appear, as had been well observed by Bernoulli, that Newton possessed before him the infinitesimal characteristic and algorithm, although it would have been easy to have found it if he had been so disposed, just as it would have been easy for Apollonius to have discovered the theory of curve lines of Descartes. He complained that his opponents had attacked his candour by forced and unfounded interpretations of his words. The question was the calculus of differences, and his opponents made it turn entirely upon series, where Newton had no difficulty in going before him. He maintained that he had found for himself a general method for series, and that he had no need of Newton's method of extractions. There were other grounds of complaint, such as, that only extracts from letters had been given in the *Commercium Epistolicum*, whereas the entire letters should have been published. Throughout the whole, which is a postscript to a letter, he manifests much chagrin; and he concludes with proposing this problem, intended, he says, to feel the pulse of the English analysts: To find a line which shall cut perpendicularly all curves of a determinate series, and of the same kind; for example, all hyperbolas, which shall have the same vertex and centre. This he desires the abbé to propose as from himself, or a friend.

In the abbé's reply to this letter he informed Leibnitz that he had delayed writing until he could at the same time send the answer which Newton had given to his postscript. He tells him that he had read the *Commercium Epistolicum*, and the originals of the letters which it contained, and, on the whole, he inferred that, setting aside matters foreign to the dispute, the only question at issue was, whether Newton had found the Calculus of Infinitesimals, or Fluxions, before, or after him? The abbé says, you published it first, it is true; but you admit that Newton allowed much to transpire in the letters which he wrote to Oldenburgh and others. This has been proved at length in the *Commercium* and its extract; what is your answer? This is what the public requires, to form a correct opinion on the matter. The abbé further informs Leibnitz that his friends believe he ought to give an answer, if not to Keill, at least to Newton himself, who, in the letter which the abbé had received from him to be communicated to Leibnitz, had challenged him in express terms. In a spirit of friendship and good sense, he further adds, that he wishes to see a good understanding between them, that the public will profit but little by their disputes, and that the additions to knowledge which they prevent are a pure loss to posterity. He moreover tells him that the king, George I., had desired to be informed of all that had passed between Newton and him. From this we may judge what an interest was excited in the public mind by a dispute which, even at this day, few could perfectly understand. The answer which Leibnitz gave to the abbé's friendly advice was, that he had put his letters, and Newton's, with his own answers to them, into the hands of Mr Remond at Paris, with a view to have a neutral and impartial opinion as to the matters in dispute. The whole were then to be submitted to the Abbé Varignon and other members of the Royal Academy of Sciences, and afterwards sent to England. In his answers he disavowed the sense which the English mathematicians had extracted from the assertion of the Leipsic journalists, namely, that Newton employed and always had employed fluxions for the differentials of Leibnitz, which they understood to mean that Newton had availed himself of Leibnitz's method, only substituting fluxions for differentials. It was from this passage that the English had declared Leibnitz to be the aggressor, in having abetted an attack of Newton; but Leibnitz declared the English interpretation to be full of malignity towards him, and that the sentence in the *Leipsic Acts* (*Pro differentiis Leibnitianis D. Newtonus adhibet semperque adhibuit fluxiones*), meant that Newton had employed fluxions after having seen his differences, and also before he had seen them.

We believe enough has been detailed to show that, besides a desire to arrive at truth, there was infused into this controversy the jealousy of two rivals for the glory of a great discovery; and, in addition, the spirit of partizanship of their respective admirers, and that natural feeling which induces men of different countries to exalt their own nation, although sometimes at the expense of their neighbours. It is not wonderful, then, that at the time this controversy was at its height, men were greatly divided in their opinions.

It is now impossible to obtain absolute certainty as to the question, whether Leibnitz derived any aid from the discoveries previously made by Newton, which, to a certain extent, were made known to the scientific world. It may therefore be some satisfaction, in the want of perfect evidence, to have the judgment of Montucla, the historian of the mathematics, on this subject. "In regard to the principle of fluxions," says he, "there are only three places of the *Commercium Epistolicum* which treat of it with sufficient clearness to prove that Newton had found it before Leibnitz, but I believe too obscurely to take from him the merit of the discovery. One of these is a letter from Newton to Oldenburgh, who had remarked to him that Slusius and Gregory had found a very simple method of tangents. Newton answered that he conjectured what it was, and he gave an example, which is in effect the same thing as these two geometers had found. He added that it was but a particular case, or rather a corollary to a method much more general, by which tangents to all sorts of curves, whether geometrical or mechanical, might be found without laborious calculation. He repeated the same thing, without explaining himself further, in his second letter, which has been already mentioned, and he concealed the principle under transposed letters. The only writing in which Newton had allowed any thing of his method to transpire is his *Analysis per Equationes numero Terminorum infinitas.* He there briefly and obscurely reveals his principle of fluxions. It cannot be denied that the principle and method were there indicated; but it is not certain that Leibnitz had ever seen the passage. His adversaries have never said that it had been communicated to him by letter; they have merely thrown out a suspicion that Collins might have communicated it to him in his second journey to London. Indeed the suspicion is not altogether void of probability, inasmuch as Leibnitz admitted that in his interview with the secretary he had seen a part of his epistolary correspondence. I believe, however, that it would be rash to pronounce upon this. There might have been grounds for suspicion if Leibnitz had merely given a few essays of his new calculus; but when we consider the improvements he made, as appears by the number of pieces he contributed to the *Leipsic Acts,* it seems probable that he owed his calculus to his own genius, and his efforts to divine the nature of a method by which Newton had made so many fine discoveries. This is the more probable, as from the method of tangents of Barrow to the differential calculus, the step is not too great to have been made by a power of mind of which Leibnitz had given so many proofs."

If it had been true, as the British mathematicians alleged, that Leibnitz had taken his calculus from that of Newton, it would have been a very remarkable circumstance that such a long period should have elapsed between his first putting forth his pretensions to the honour of the invention, and the denial of Newton and his friends. This is a thing uncommon in the history of contested claims to discovery, when both the claimants are alive and all the facts known. It is also remarkable that Newton, while in the prime of life, did not of his own accord bring forward a charge of plagiarism against his contemporary. On the contrary, in the first edition of his *Principia,* which appeared in 1687, he expressly admitted Leibnitz's claim; and this admission is found even in the edition of the *Principia* published in 1713. It is now well known, that before the period of the controversy between Newton and Leibnitz, the mind of the former had at one time been in a state which rendered him unfit to draw correct conclusions from the ordinary incidents of life; witness his letters to Mr Pepys and Mr Locke in September 1693 (Brewster's *Life of Newton*). At this time he seems to have laboured under great bodily indisposition, from which he afterwards in appearance recovered; indeed it may be doubted whether his temper was so equal and mild in the latter period of his life as has been represented by his biographers. A collection of letters which passed between Flamsteed the astronomer and Abraham Sharp the celebrated calculator, which have lately come into the possession of the Astronomical Society of London, prove that Newton, in conjunction with Halley, opposed Flamsteed in the publication of his *Historia Cœlestis,* a work of the highest merit, and the result of the labour of his life, with a pertinacity of purpose which is by no means an amiable trait in his character. It is certain that Newton entertained towards Leibnitz a very different feeling at one period of his life, from that which he in the end evinced. In the edition of the *Principia* 1713, and those which preceded it, he says, "Ten years ago, in a correspondence with Mr Leibnitz, I informed him that I had a method of determining maxima and minima, of drawing tangents, and resolving similar problems, which applied alike to rational and irrational terms, but concealed it under transposed letters. He answered that he had found a like method, which he communicated, and which differed from mine only in the terms and the signs, and in the way of conceiving quantities to be generated." This concession was liberal, and worthy of Newton. However, in the edition of 1726, he retracted this act of justice, having struck out the passage, as Montucla assures us, with his own hand. The historian of the mathematics, however, finds an excuse for this harshness in the treatment which Newton had received from Leibnitz's friends.

The circumstance of the calculus having had two distinct origins, had the inconvenient effect of giving it two different forms and names. Newton at different times used different notations before he finally adopted that which has been followed by the English mathematicians. Leibnitz and his followers employed one somewhat different; and each sect pertinaciously adhered to the example set by its leader. There was a still greater difference in the view which each party took of quantity, and the way in which it may be generated. Newton conceived geometrical magnitudes to be generated by continued motion, a line by a point in motion, a surface by a moving line, a solid by a moving surface, an angle by a line turning about a point, and so on. It is evident, that by assuming geometrical quantities as the representatives of time, force, and whatever can be expressed by number, these can be conceived to increase or decrease according to the same laws as their geometrical representatives. His calculus therefore consisted of two parts:

1*st,* Supposing two quantities to have a given relation to each other (for example, the one to be always equal to the square of the other), and the rate of increase of one of them at any instant of time to be known; to find the rate of increase of the other at the same instant. These rates of increase were called the *fluxions* of the quantities; and the rules for their determination constituted the *direct method of fluxions.*

2*d,* The second part was the reverse problem, in which the relation between the rates of increase of two quantities which depended the one on the other, being given, it was required to discover the relation of the quantities. This was the inverse method.

Leibnitz at first supposed quantity to increase by the addition of some indefinite portion of a quantity of the same kind, and his *differentials* were quantities proportional to the instantaneous changes in the greatness of the quantities thus generated. He afterwards found it shorter to introduce directly these instantaneous changes into his calculus under the name of infinitely little differences (*infiniment petites*). These however he did not regard as absolute *zeros,* but only as not comparable to finite magnitudes. His calculus had, like Newton's, two parts, the *differential calculus,* which gave rules for deducting the relation of the differentials of quantities from that of the quantities themselves, and the *integral calculus,* which resolved the reverse problem, or discovered the relation of the quantities when the relation of their differentials was known. This corresponded to the inverse method of fluxions, as the differential calculus corresponded to the direct method.

There is this distinction, then, between the two methods:

Introduction.

Newton's fluxions are any finite quantities which have to each other the ratio of the velocities, or degree of quickness with which the quantities are generated. The differentials of Leibnitz are infinitely small quantities, a creation of the mind more removed from ordinary apprehension than the finite representatives of fluxions. This distinction has often been urged in favour of the superiority of Newton's calculus. On the other hand, Newton has introduced time into his calculus. Now this is an element foreign to geometry, and belonging to mechanics, a quite distinct branch of science. The metaphysical distinctions between the two forms of the calculus have had but little influence on its progress. Whichever of the two forms is chosen, the rules are the same; and so also are the difficulties to be overcome.

Some time elapsed before the newly invented calculus was actively employed. At length Leibnitz, to rouse the attention of geometers, proposed in 1687 this problem: To determine the curve along which a heavy body must descend, so as to approach by equal distances in equal times to a horizontal plane. Huygens was the first to resolve the problem. He showed what was the nature of the curve; but he did not give his demonstration. James Bernoulli also resolved the problem by the differential calculus, and published his analysis in the *Leipsic Acts*. His younger brother John united himself in a close friendship with Leibnitz, and continued throughout life his coadjutor and staunch defender. He made the calculus known in France, where he resided for a time, and gave lessons to the Marquis de l'Hôpital. Part of these form the *Analyse des infiniment Petits*, a work which bears the name of the marquis, with but a slight acknowledgment in the preface of the share which his preceptor had in its composition. Indeed it was almost entirely his; and of this injury Bernoulli complained justly, but privately, in his correspondence with Leibnitz. The remaining lessons, which teach the integral calculus, are given in the collection of Bernoulli's works, published in 1742. The whole form an excellent exposition of the principles of the calculus, and contain some of its finest applications.

The continental mathematicians who were remarkable for their skill in the differential calculus were at first few in number. They might be nearly all included in the names of Leibnitz himself, James and John Bernoulli, De l'Hôpital, and Varignon. They were, however, remarkably active, particularly the Bernoullis, whose writings have contributed powerfully to its advancement.

The inventor of the fluxional calculus seems to have taken but little interest in its extension. His treatise on quadratures did not appear till 1706; and his work on fluxions was not published in his life time, but appeared in 1736, nine years after his death. He had however fully availed himself of its power in the composition of his *Principia*, without revealing to the full extent the nature of the instrument with which he wrought, but establishing the truth of his propositions by synthetic demonstration, after the manner of the ancient geometers. Probably this was done in deference to the taste of that time; for a contemporary writer, Hermann, in following his example in the composition of his *Phoronomia*, assigned to Leibnitz as a reason, that the geometrical method was likely to be better understood than the analytical in Italy. This way of proceeding is now, however, disused by the best writers, and replaced by the more legitimate and undisguised use of the calculus.

The extensive views which the new calculus opened up, afforded the means of resolving problems which had baffled the skill of the earlier mathematicians, and suggested many new ones, which without its aid would have been quite intractable. The cycloid and the catenary, curves which had eluded the penetrating mind of Galileo, were more fully comprehended; many new ones were suggested, and the cultivators of the calculus challenged each other to an investigation of their properties. There is an elegant class of problems which relate to the greatest and least values of quantities. Some of these, called problems of *maxima* and *minima*, can be resolved by the ordinary geometry and algebra; but there is a class which lies beyond the dominion of these, and to it belongs the solid of least resistance, the curve of swiftest descent, and, in general, the problems called *isoperimetrical*, one of the simplest of which is to find the nature of the line which, being given in length, shall comprehend the greatest possible space. These formed the subject of a warm but honourable contest between the two Bernoullis, brothers; and their investigation laid the foundations of that branch of the calculus, the highest, which has been formed into a theory by the labours of Euler and Lagrange, under the name of the *Calculus of Variations*.

Among the early cultivators of the calculus in Britain we may reckon Cotes, the friend of Newton, who died at the early age of thirty-four (his *Harmonia Mensurarum*, and other writings, indicate a genius of the highest order), De Moivre, Taylor, Craig, David Gregory, and Stirling. It must, however, be confessed, that the continental school in the course of time advanced before that of Britain, as well in the number of its disciples, as in their high mathematical genius and the importance of their discoveries. John Bernoulli had two sons, Nicolas and Daniel, who rivalled their father's skill in the applications of the calculus; and these had as condisciples Hermann and Euler. This last mathematician has carried the subject to a point of perfection far beyond what it had attained in the hands of those that had gone before him.

Amongst the means by which the improvement of the calculus has been promoted, we may reckon the problems which passed between the British and continental mathematicians as challenges to each other, in answering which Newton himself condescended sometimes to enter the lists. The doctrine of infinite series, a branch of the mathematics of English origin, gives powerful aid to the calculus in its greatest difficulties; but, legitimately, its assistance ought not to be called in if the problem admit of being resolved in finite terms. The English sometimes failed in the observance of this most proper condition of a good solution, and thus gave rise to reproaches from their opponents, which in at least one instance were not unjustly incurred by Newton himself. In the course of this warfare, Keill, the champion of the English, proposed as a challenge to John Bernoulli, to determine the nature of the curve which a projectile describes in a medium resisting as the square of the velocity. Bernoulli soon resolved the problem, not only in the case proposed, but also when the resistance was as any power whatever of the velocity. He then proposed to put his solution into the hands of some confidential person in London, provided that Keill would deliver his solution to the same person. Keill, however, had upon trial not been able to resolve the problem, and therefore preserved a profound silence, and made himself, by his boasting and failure, quite ridiculous. The triumph of Bernoulli was complete, and he did not miss the opportunity of bestowing severe castigation on his humbled adversary, recollecting, we may suppose, the treatment which his deceased and lamented friend Leibnitz had received from him and his friends.

As another proof of the spirit and rivalry of the supporters of the two analytical theories, we may mention that Brooke Taylor proposed a problem in the integral calculus to all geometers not English, and sent it to Mr Montmort to be communicated to the foreign geometers.

Introduction.

Notwithstanding the general terms of the challenge, it was well understood to be particularly aimed at John Bernoulli, who in return offered to wager fifty Louis that he would resolve the problem, and to stake fifty more that he would propose a problem which he himself could resolve, but which Taylor could not. The English mathematician did not think it prudent to accept the offered condition. Indeed it was a complaint against the English geometers, that although they made no scruple of trying to puzzle foreigners with difficulties, they rarely responded to the counter challenges proposed to themselves.

Perhaps there never was a considerable invention or discovery which had not to encounter opposition; sometimes from the slowness with which the human mind yields to the force of truth when opposed to long-received opinions, and sometimes from less excusable causes, such as mistaken or interested views, or mere jealousy excited by the fame of the inventor. The new calculus had in the very outset its opponents, such as the Abbé de Catelan, a zealous Cartesian, who declared that it would be better to extend the principles of the Cartesian geometry than to seek for new methods; and this was said in the preface of a book composed on the principles, somewhat disguised, of the very calculus of which he was an opponent. It had another adversary in Nieuwentiit, a man who had written some tolerable works on morality and religion, but who had but small pretensions to be regarded as a geometer. Catelan was satisfactorily answered by De l'Hôpital, as was Nieuwentiit by Leibnitz, and afterwards by Bernoulli and Hermann, who proved that this adversary of the calculus really did not know what he opposed.

The calculus had a more formidable enemy in M. Rolle, a skilful algebraist and indefatigable calculator, but a man full of confidence in his own notions, rash in forming his opinions, and jealous of the inventions of others. He attacked the certainty of its principles, and he attempted to show that its conclusions were at variance with those obtained by methods previously known, which were acknowledged to be correct. His attack was repelled by Varignon, who completely obviated the objections to the truth of the principles, and further showed that the supposed discrepancy between its conclusions and those obtained by other methods, were mistakes he had committed from haste and inadvertence. These disputes occupied the French Academy a considerable part of the year 1701. The members were chiefly geometers considerably advanced in years, who had been long accustomed to other methods, and were therefore not much disposed to receive new doctrines. Some took no part in the dispute, yet were not sorry to see a storm raised against a theory for which they had no great liking, and took no means to allay it; others, more under the influence of their passions and prejudices, yielded to these, and declared open war against it. In this state of things the best course was supposed to be that of hearing all which could be said for and against the calculus. The academy was long involved in the dispute. Rolle brought forward objection upon objection; and although Varignon continually obviated them, yet the former always claimed the victory. In the end the dispute degenerated into a real quarrel, and commissioners were appointed to decide on it. These were Père Gouye, MM. Cassini and de la Hire, who, however, pronounced no judgment; but the public opinion, or at least the opinion of geometers, was in favour of Varignon. The first controversy thus ended, or at least was suspended, for want of a decision from the commission; but Rolle, the champion of the opponent of the calculus, soon renewed hostilities. Its defence was next taken up by M. Saurin. The ground of attack was the indefinite form which the calculus gives for the subtangent of a curve at the point where two branches intersect each other, and which in this case is expressed by the fraction $\frac{0}{0}$. Saurin's answer was satisfactory; but Rolle, intrenched in masses of calculation, obstinately maintained the combat. The academy was again appealed to. The Abbé Bignon, who conducted its affairs, undertook to decide the controversy, with the assistance of MM. Gallois and De la Hire, two judges by no means favourable to Saurin. They gave no absolute judgment; but recommended to Rolle to conform more strictly to the rules of the academy, and to Saurin to forgive the proceedings of his adversary. Rolle suffered in the estimation of competent judges; he, however, afterwards did justice to the calculus, by acknowledging that he had done wrong in opposing it, and admitting that he had been urged forward by the instigation of malevolent persons, one of whom was the Abbé Gallois; and his demise in 1707 accordingly put an end to the controversy.

In England the Newtonian calculus had to sustain an attack on its principles from a writer of first-rate talents, Berkeley, bishop of Cloyne. The circumstances which led to it are curious. Mr Addison had given the bishop an account of the behaviour of their common friend, Dr Garth, in his last illness, which was highly unpleasing to these two advocates of revealed religion; for when Addison began to discourse with Garth on a future state, "Surely," said the latter, "I have no reason to believe these trifles, when my friend Dr Halley, who has dealt so much in demonstration, has assured me that the doctrines of Christianity are incomprehensible, and religion itself an imposture." The bishop therefore took up arms against Halley, and in the year 1734 addressed to him, as an infidel, a discourse called The Analyst, the object of which was to prove that mathematicians acted inconsistently in objecting to mysteries in faith, seeing that they did not hesitate to admit much greater mysteries, and even falsehoods, in their own science; and he chose the principles of the doctrine of Fluxions, as laid down by Newton and adopted by his followers, to prove the truth of his proposition. It may be supposed that so able a writer would not fail to make an impression on the public mind. But the mathematicians were not slow in coming forward in defence of the doctrines of their chief. In the same year came out a tract with this title: "Geometry No Friend to Infidelity, or a Defence of Sir I. Newton and the British Mathematicians, by Philalethes Cantabrigiensis," supposed to be Dr Jurin. As usual the attack was renewed, and again repelled by the same hand. Other defences of Newton appeared, one of the best of which was from the pen of Benjamin Robins; it was entitled A Discourse concerning the Nature and Certainty of Sir Isaac Newton's Method of Fluxions, and of Prime and Ultimate Ratios. But the most important result of this controversy was A Treatise on Fluxions from the pen of Colin Maclaurin, professor of mathematics in the university of Edinburgh, printed in 1742. This defence of the principles of Newton's views, expressly intended to obviate all objections, is quite satisfactory. The treatise is indeed considerably prolix; but this was a consequence of the circumstances in which it was composed. It however contains a great deal more than a mere theory of fluxions. We have in it some of the finest applications of analysis to the principal problems which had been agitated amongst geometers from the invention of the calculus to the time in which the work appeared.

By the middle of the century the calculus proceeded with a rapid march of improvement. Euler in 1744 greatly enriched it by his solution of the Isoperimetric Problem (*Solutio problematis isoperimetrici latissimo sensu accepti*), a theory which he afterwards wrought up into the Calculus of Variations, and which has been still further improved by Lagrange. Brooke Taylor, by his *Methodus Incrementorum*, had extended the foundations, and even proceeded a great way in the structure, of a kindred calculus, that of finite differences. Stirling had followed in the same path in his *Methodus Differentialis;* and Euler had opened a new field for discovery in the calculus of partial differences, in which D'Alembert followed his steps, and carried the subject further. The same period abounded in good writers. In this country Demoivre, Simpson, Landen, and Waring, stand among the foremost in the list for the originality of their views; on the continent Ricatti, Clairaut, Fontaine, and others, followed in the train of Euler and the Bernoullis.

It is a curious fact in the history of mathematics, that there are instances of ladies who have applied their talents to its study and improvement with much success. Hypatia, the daughter of the ancient geometer Theon, is one notable instance. Unfortunately we have no vestiges of her writings by which we might form an estimate of her proficiency in a science which at first sight seems not to have many attractions for the female mind. We have another instance in an Italian lady, Maria Gaetana Agnesi, who was actually professor of mathematics in the University of Bologna in the year 1748; and how well she was qualified for the office appears from her Analytical Institutions, a work of great excellence on algebra, the theory of curve lines, and the differential calculus, composed for the instruction of the youth of Italy. This work is so excellent, that Bossut, a French mathematician of great eminence, translated the part on the differential calculus into French, and incorporated it with his Course of Mathematics, as the best treatise he could find on the subject. There is also an English translation by the Rev. John Colson, Lucasian professor of mathematics in the university of Cambridge. Her countryman Frisi, a most competent judge, mentions her in enumerating the mathematicians of Italy, and bestows great praise on her work, calling it *opus nitidissimum, ingeniosissimum, et maximum certe opus quod hactenus ex feminæ alicujus calamo prodierit.* At the present time we have another admirable instance of a lady who has surmounted the difficulties of the calculus. Mrs Somerville, in her work entitled *Mechanism of the Heavens*, London, 1831, has enriched English literature with a treatise on physical astronomy, in which the different branches of the calculus are combined with the most refined theories of mechanics. Her book does her infinite credit, and indeed is highly honourable to the whole female sex.

Geometers have differed in opinion as to the best way of working up the principles of the calculus into a system. Newton, as has already been stated, employed the theory of motion as the means of connecting its doctrines with the principles of the ordinary algebraic analysis. Leibnitz, again, with the same view, conceived quantity as passing from one degree of magnitude to another by the continual accretion of infinitely small parts. The mind finds no great difficulty in distinctly apprehending the subject in its simplest state either way. Objections have, however, been taken to both, and attempts made to substitute a better. Euler considered the infinitely small quantities of Leibnitz as absolute zeros, that have to each other ratios derived from those of the vanishing quantities which they replace. D'Alembert proposed to make the basis of the calculus the consideration of the ratios of the limits of the quantities. An English mathematician, Landen, has substituted for the Newtonian method of fluxions another purely analytical. His views are contained in a work entitled The Residual Analysis, a new branch of the Algebraic Art, by John Landen, 1764. Lastly, Lagrange, in the Memoirs of the Berlin Academy for 1772, proposed to make the calculus altogether independent of the consideration of infinity, and to rest on principles purely analytical, thus connecting it with the doctrines of the ordinary algebra. He has since realised and extended his views in his *Théorie des Fonctions Analytiques*, also in his *Leçons sur les Calcul des Fonctions;* works which, from their excellence and the celebrity of their author, have formed a new era in the history of the calculus.

The twofold origin of the calculus, besides placing its principles on different foundations, gave it also two different forms of notation; and in this state it continued during the whole of the eighteenth century, to the great inconvenience of mathematical students, and, we may add, to the hindrance of the progress of science. A change, however, has taken place within the last twenty years; during that period some British geometers, imbued with the mathematics of the continent, adopted also its notation in preference to that of the followers of Newton, and employed it publicly in their researches. This spirit of innovation in time took possession of the minds of the junior members of the university of Cambridge, and now we may say that it has completely supplanted the native notation. We have retained the name of Fluxions, because, from the changes which have taken place in the way of treating the subject since the days of Leibnitz and Newton, it seems to be as proper as the term differential. It is otherwise with the notation. This is consecrated by its having been employed in the writings of Euler, D'Alembert, Lagrange, and other great masters in mathematical science; and besides, it has advantages over the other in point of symmetry and compactness, and the established reputation of a whole century of useful service. It is true, the late illustrious Lagrange laid it aside in his attempt above mentioned to new-model the calculus; but subsequent writers, in extracting what was excellent from his works, have in general invested his views with the ordinary notation of the continent. In the following treatise we shall conform to this beneficial alteration.

Writers on the Infinitesimal Calculus, before the Invention of the Method of Fluxions.

Kepler, Nova Stereometria Doliorum Vinariorum	1615
Cavalieri, Geometria Indivisibilium	1635
——— Exercitationes Geometricæ Sex	1647
Roberval, Traité des Indivisibles. Mém. de l'Acad. des Sciences	1666
Descartes, in his Letters and Geometry, book 2d, and his mathematical works	1637
Torricelli, De Sphæra, et Solidis Sphæralibus	1644
Gregory St Vincent, Opus Geometricum de Quadratura Circuli	1647
Wallis, Arithmetica Infinitorum	1655
Fermat, Opera Varia Mathematica	1679
Mercator, Logarithmo-Technia	1668
James Gregory, Vera Circuli et Hyperbolæ Quadratura	1668
Brouncker, Squaring the Hyperbola, *Phil. Trans.* London	1668
Huygens, Opera; Horologium Oscillatorium	1673, 1724
Barrow, Lectiones Geometricæ	1670
Slusius, Tangents to all Geometrical Curves, *Phil. Trans*	1672
Wren, Rectification of the Cycloid, *ibid*	1673
Ismael Bullialdus, Arithmetica Infinitorum, libri. vi	1682
Leibnitz, Quadrature of the Circle, *Leips. Acts* and *Phil. Trans.*	1682
Viviani, Exerc. Math. de Formatione et Mensura Fornicum	1692

Writers on the Fluxionary or Differential Calculus.

Newton, De Analysi per Æquationes numero terminorum Infinitas, circulated in manuscript in 1669, and printed in the *Commercium Epistolicum*, 1712. Also contained in a volume edited by W. Jones, and entitled Analysis per Quantitatum Series, Fluxiones, ac Differentias	1723
——— Principia, lib. ii. sect. iii. lemma 2	1687
——— Tractatus de Quadratura Curvarum, published with his Optics	1704
——— The Method of Fluxions	1736
Leibnitz, Nova Methodus pro maximis et minimis itemque tangentibus. *Leipsic Acts*	1684
James Bernoulli, Analysis Magni Problematis Isoperimetrici; *Acta Erud.* See also his Works	1744
John Bernoulli, *Acta Erud. Leip.*; also *Mémoires de l'Acad. des Sciences*	1742
Leibnitz and Bernoulli, Commercium Phil. et Math. 2 vols. 4to	1745
Demoivre, Use of Fluxions in Geometric Problems, in the *Phil. Trans.*	1695
De l'Hôpital, Analyse des Infiniment Petits	1696
David Gregory, On the Catenary, *Phil. Trans.*	1697
Carré, Méthode pour la Mésure des Surfaces	1700
Craig, Solid of least Resistance and Curve of quickest Descent, *Phil. Trans.*	1700
—— De Calculo Fluentium	1718
Cheyne, Fluxionum Methodus Inversa	1703
Harris, Lexicum Technicum	1704
Hayes, A Treatise on Fluxions	1704
Ditton, Institution of Fluxions	1706
Manfredi, De Construct. Equat. Diff. primi gradus	1707
Taylor, Methodus Incrementorum	1715
Cotes, Harmonia Mensurarum	1722
—— Estimatio errorum in mixta Mathesi	
Riccati, Animad. in Equat. differentiales, secundi gradus, *Acta Erud*	1724
Clarke, An Institution of Fluxions	1726
Hermann, De Constructione Equationum Differentialium, *Comm. Petrop*	1726
Fontenelle, Eléméns de la Géométrie de l'Infini	1727
Clairaut, Determinatio Curvæ ejusdem Differentialis, *Acta Erud*	1729
Demoivre, Miscellanea Analytica	1730
Stone, Method of Fluxions	1730
Hodgson, The Doctrine of Fluxions	1736
Deidier, Le Calcul Différentiel	1740
Simpson, A Treatise on Fluxions	1737 and 1750
Maclaurin, A Treatise on Fluxions	1742
Emerson, The Doctrine of Fluxions	1743
Donna Agnesi, Instituzioni Analitiche	1748
French translation of the same work by Cousin	1775
An English translation by Colson	1801
Euler, Methodus Inveniendi Lineas Curvas maximi minimive proprietate gaudentes	1744
—— Introductio in Analysin Infinitorum	1748
—— Institutiones Calculi Differentialis	1755
—— Institutiones Calculi Integralis	1768–70
The titles of Euler's academical memoirs, of which there is a very great number on the Differential Calculus, are given in the edition of his *Calculus Differentialis*, printed at Pavia in 1787, and occupy thirty-two quarto pages.	
Walmesly, Analyse des Mésures des Rapport et des Angles	1750
Stirling, Methodus Differentialis	1753
Bougainville, Traité du Calcul Intégral	1754
Landen, Mathematical Lucubrations	1755
——— The Residual Analysis	1764
Landen, Mathematical Memoirs	1780
Saunderson, Method of Fluxions	1756
Lyons, Treatise of Fluxions	1758
Kaestner, Separatio Indeterminat. in Æquat. Diff.	1756
D'Alembert, Opuscules Mathématiques	1761–80
Robins, Mathematical Tracts	1761
Waring, Miscellanea Analytica	1762
——— Meditationes Analyticæ	1776
Condorcet, Du Calcul Intégral	1765
Le Seur et Jacquier, Elémens du Calcul Intégral	1768
Lexell, Methodus Integrandi Æq. Diff. *Comm. Petrop.*	1769
Fontaine, Traité du Calcul Diff. et Intégral	1770
Gianella, De Fluxionibus et earum Usu	1771
Cousin, Leçons du Calcul Différentiel, &c	1777
La Place, l'Usage du Calcul aux Différences partielles, *Mém. de l'Acad.*	1777
Condorcet, De Integ. cujusdam Æquationis, *Comm. de Bonon.*	1783
Malfatti, Delle formale differentiali la cui integrazione dipende dalla rettificatione delle sezione coniche	1784
Paoli, Memoria sull' equazione a differenze finite e parziali	1784
Monge, Sur le Calcul Intégral des Equat. aux Dif. partielles, *Mem. de l'Acad*	1784
Charles, Recherches sur le Calcul Intégral, *Mem. de l'Acad.*	1784
L'Huillier, Exposition des Principes de Calcul Supérieur	1786
——— Principiorum Calculi Diff. et Integ	1795
Mascheroni, Annotationes ad Cal. Integ. Euleri	1790
Tabiescen, Principia atque Historia Calculi Differ. et Integ. nec non Methodi Fluxionum	1793
Lagrange, Calcul des Variations, *Mis. Taur.* vol. ii. and iv.	1760–69
——— Théorie des Fonctions Analytiques	1797
2d edit	1813
——— Leçons sur le Calcul des Fonctions, 2d edit	1806
The titles of his Memoirs, inserted in Academical Collections, are given in his Mécanique Analytique, second edition	1795
Vince, Principles of Fluxions	1797
Carnot, Réfléxions sur la Métaphysique du Calcul Infinitesimal	1797
Bossut Traité du Calcul Différentiel	1798
Lacroix, Traité du Calcul Différentiel et du Calcul Intégral, first edit. 1797, second	1810–19
Abrogast, Du Calcul des Dérivations	1800

The preceding catalogue contains the names of the principal improvers and cultivators of the calculus, from its first invention to the end of the last century. However, it does not contain all their writings; to have enumerated these would have extended the catalogue to too great a length. Almost all the improvements of the calculus were first given in the form of academical memoirs, from which they have been drawn, and incorporated into the systems that have from time to time been published. The great repertories in which it is contained are the writings of Newton, Cotes, Demoivre, the Bernoullis, Maclaurin, Simpson, Euler, D'Alembert, Lagrange, Legendre, La Place, Monge, Poisson, Gauss, Ampère, Ivory, &c. From these have been constructed the treatises of De l'Hôpital, Bougainville, Le Seur and Jacquier, Cousin, and others, which were the most complete at the different periods when they appeared. At this time the most extensive treatise is the second edition of Lacroix, which came out between 1810 and 1819. In the present century there have been published in France treatises by Garnier, Du Bourguet, Boucharlat, Cauchy, and others which we have not seen. In Britain we have had treatises by Woodhouse, Dealtry, Lardner, Jephson, Young, Thomson, and others. The university of Cambridge, long infertile, now teems with treatises on the subject, such as those of Brown, Coddington, Earnshaw, Hymer, Jarret, Millar, Myers, and Peacock. There are, besides, treatises on the calculus in courses of mathematics, such as the Elementi d'Algebra of Paoli, the Cours des Mathematiques of Bezout, a like work by Francœur, &c. There have also been works constructed for the benefit of students, which may be used with any treatise on the subject, such as the excellent collection of examples by Peacock, Herschel, and Babbage, which was intended as an accompaniment to an English translation of an abridgment of Lacroix's treatise; and the integral tables of Hirsch, which have been translated from the original German into English.

There is a branch of the calculus of great interest, which of late has engaged, and will probably long engage, the attention of mathematicians; we mean the subject of *Elliptic Transcendents.* This theory originated in the discovery of a very remarkable property of the ellipse and hyperbola by Fagnano, an Italian mathematician, who first showed that arcs of these curves can be assigned, of which the difference is expressible in finite algebraic terms. This most interesting subject has been discussed by the following writers:

Fagnano, Produzioni Mathematiche, tom. ii. p. 336...1750
Euler, Calculus Integralis, tom. i. sect. ii. and tom. iii. supp.
Bossut, Leipsic Acts, 1754; Mém. de Math. et de Phys. tom. iii.
Landen, Lond. Phil. Trans. 1775; and Mathematical Lucubrations..........1780
Legendre, Mém. de l'Acad. des Sciences, 1786; Mémoire sur les Transcendantes Elliptiques, 1792. (There is an English translation of this memoir in Leyburn's Mathematical Repository, vols. ii. and iii. new series.) Exercices de Calcul Intégral, 3 vols.; Schumacher's Journal, Nos. 123, 127, 130.
——— Traité des Fonctions Elliptiques............1825
——— Miscell. Taur. tom. iv.; Théorie des Fonct. Analytiques, 2d edit.
Ivory, New Series for the Rectification of the Ellipse, Trans. R. S. Edin. vol. iv.; Fagnani's Theorem made more general, Leyburn's Math. Repository, vol. i. new series; On the Theory of the Elliptic Transcendents, Trans. R. S. Lond. 1831.
Wallace, Formula for the Rectification of an Ellipse, &c., Trans. R. S. Edin. vol. v.
Woodhouse, Integration of Certain Differentials, Trans. R. S. Lond. 1804.
Brinkley, Demonstration of Fagnani's Theorem, Trans. Irish Acad. vol. ix.
Abel, J. Crell's Journal, vol. ii.
Jacobi Fundamenta Novæ Theoriæ Functionum Ellipticarum..........1829
Plana, Memoir read in the Turin Academy..........1828

PART I.

DIRECT METHOD OF FLUXIONS, OR DIFFERENTIAL CALCULUS.

1. In the application of algebra to the theory of curve lines, some of the quantities under consideration are conceived as having always the same magnitude as the parameter of a parabola, and the axes of an ellipse or hyperbola; others again are indefinite in respect of magnitude, and may have any number of particular values; such are the co-ordinates at any point in a curve. This difference in the nature of the quantities has equally place in various theories of the pure and mixed mathematics, and it naturally suggests the division of all quantities into two kinds; namely, such as are constant, and such as are variable.

A constant quantity is that which is supposed to have always the same value. A variable quantity, again, is that which may change its value by increasing or decreasing, so that in passing from one degree of magnitude to another it will have had in succession every possible intermediate magnitude.

Thus, in a circle, the radius is a constant quantity, and any arc of the circle, also its cosine, sine, tangent, secant, &c. are variable quantities. In the ellipse, the axes or semiaxes are considered as constant; and the co-ordinates to any point in the curve, and in general any lines or spaces or angles which in the same ellipse admit of different values, are variable. So again in the parabola, the parameter is constant, and the co-ordinates to any point in the curve, also any arc of the curve, and the space contained by that arc and the co-ordinates, are to be regarded as variable.

In what follows, we shall in general call constant quantities simply *constants,* and variable quantities *variables.*

It is usual to denote constants by the letters $a, b, c,$ &c. towards the beginning of the alphabet, and variables by the letters $x, y, z,$ &c. towards the end.

2. One quantity is said to be a *function* of another when they are so related that the latter being supposed to change its value, the former also changes its value. Thus, in geometry, the radius of a circle being constant, the cosine, the sine, the tangent, the secant, &c. are functions of the arc. On the other hand, the arc may be considered as a function of any one of these quantities. In mechanics, the force by which a body is urged forward, the space it has passed over, and its velocity at every instant, may all be regarded as functions of the time.

In this algebraic expression,

$$y = \frac{a+x}{a-x},$$

in which a is a constant and x a variable, the quantity y is regarded as a function of x, which is called the *independent* variable. Here y is expressed by x; but by resolving the equation, x may be expressed by y thus:

$$x = \frac{a(y-1)}{y+1};$$

the quantity x is now a function of y. In either case, the constants a and 1 are not considered. In these examples,

$$u = a + bx + cx^2,$$
$$u = \sqrt{(a^2 + bx + x^2)},$$
$$u = \frac{a + \sqrt{bx}}{c + x^2},$$

u is a function of x.

A quantity may be a function of several independent variable quantities. Thus, in the expression

$$u = ax^2 + bxy + cy^2,$$

u is a function of the independent variables x and y.

The variety of forms of functions of a variable is endless. They may, however, be resolved into a few elementary functions such as these,

$$x^n, \quad a^x, \quad \log x, \quad \sin x, \quad \cos x.$$

The first of these, x^n, in which n is constant, and all that can be formed from it by a finite number of the elementary operations of algebra, are called *algebraic* functions; for example, this,

$$u = ax^3 + \frac{bx^2 - c^2x}{\sqrt{a^2 + x^2}},$$

which is formed by addition, subtraction, multiplication, division, and the extraction of the square root. These two, a^x, $\log x$, which cannot be expressed by a finite number of terms composed of powers of x, are called *transcendental* functions, and the remaining two, $\sin x$, $\cos x$, and such as may be formed from them, viz. $\tan x$, $\sec x$, &c. are called *trigonometrical*, also *angular* and *circular* functions.

In the last example, the value of the function u may be immediately found, if the value of x be known. Such functions are called *explicit*. There are functions, however, which require to be separated from the variable by the resolution of equations, or other means, before their value can be found; as in this example,

$$ux = \frac{u + x}{u - x},$$

in which u is supposed to be a function of x. In this case, before the value of u, corresponding to a given value of x, can be found, a quadratic equation must be resolved. Such a function is called an *implicit* function of x. On the other hand, x is an implicit function of u. By the resolution of an equation we find

$$u = \frac{1}{2}\left\{x + \frac{1}{x} + \frac{\sqrt{x^4 + 6x^2 + 1}}{x}\right\};$$

u is now an explicit function of x.

The early algebraists indicated the square root of a quantity by placing the letter r before it; thus rx meant the square root of x. The letter was afterwards changed into the sign $\surd$, and the square root of x was conveniently expressed thus, $\sqrt{x}$. In like manner, it is convenient to have a symbol which shall express generally a function of a variable, and accordingly it is now usual to express any function of a variable x by the symbol fx or $f(x)$; also by $\mathrm{F}x$, or φx. Here the letters f, or F, or φ, are considered merely as the abbreviation of the word *function*, and not as a co-efficient to the letter x. In this way we include all these expressions,

$$u = x^n, \quad u = a^x, \quad u = \log x, \quad u = \cos x, \quad u = \sin x,$$

in one general expression, viz. $u = fx$, or $u = f(x)$.

When a function depends on two variable quantities x, y, which are independent of each other, such as this expression,

$$u = ax^2 + bxy + cy^2,$$

we shall express it thus,

$$u = f(x, y).$$

Here we take no notice of the constant quantity a, b, c. A like notation may be applied when three independent variables enter a function.

3. The manner in which we propose to treat this subject requires that the reader should distinctly understand what is meant by a *limit* to the value of a variable function, or a variable ratio. In the elements of geometry it is shown that the area of a circle is less than that of any regular polygon described about it; and that the greater the number of sides of the polygon, the more nearly is its area equal to that of the circle; so that any space being given, however small, a polygon may be described about the circle, which shall differ from it by less than that space. Suppose now a series of polygons to be described about a circle, each having the number of its sides greater than that which preceded it, the double for example. These will approach continually to an equality with the circle as a *limit*, which the series, however far continued, can never absolutely reach in respect of magnitude, but from which some term, and all that follow it, may differ by less than any space assignable.

In like manner, the circle is the limit of the area of all regular polygons inscribed in it; and the circumference of the circle is the limit of the perimeters of regular polygons described in it or about it.

In our article ALGEBRA (sect. 266) it has been shown, that, putting a for an arc of a circle, the fraction $\frac{a}{\sin a}$ is always greater than an unit, but that $\frac{a}{\tan a}$ is always less; farther, that the arc being supposed to decrease continually, these fractions approach to each other, and may differ by less than any assignable quantity; therefore unity, which is always between them, is their common limit. Hence it appears, that of these three quantities, an arc, its sine, and its tangent, the ratio of any two is that of equality. In the same article it has been shown that the arc a is the limit of the fractions $n \tan. \frac{a}{n}$ and $n \sin \frac{a}{n}$, supposing the number n to be increased continually.

The geometrical series

$$1 + x + x^2 + x^3 \ldots + x^{n-1}$$

is equivalent to the function $\frac{1 - x^n}{1 - x}$ (ALGEBRA, sect. 56); when x is less than 1, and n is infinitely great, then $x^n = 0$, and the function $= \frac{1}{1 - x}$; therefore, in this case, the sum of any finite number of terms of the series will always be less than $\frac{1}{1 - x}$, but will approach to it as the number of terms increases, and may differ from it by less than any assignable quantity; hence it follows that the function $\frac{1}{1 - x}$ is the limit of the sum of the series.

By the binomial theorem

$$\left(1 + \frac{x}{n}\right)^n = 1 + \frac{x}{1} + \frac{x^2}{1 \cdot 2}\left(1 - \frac{1}{n}\right)$$
$$+ \frac{x^3}{1 \cdot 2 \cdot 3}\left(1 - \frac{1}{n}\right)\left(1 - \frac{2}{n}\right) +, \text{\&c.}$$

This is true, whatever be the numerical value of n; but suppose n to be a large number, then the factors $1 - \frac{1}{n}$, $1 - \frac{2}{n}$, &c. will differ but little from unity; and they will differ the less as n is greater. Suppose now n to be indefinitely great, then these factors may be accounted each equal to an unit; and, therefore,

$$\left(1 + \frac{x}{n}\right)^n = 1 + \frac{x}{1} + \frac{x^2}{1 \cdot 2} + \frac{x^3}{1 \cdot 2 \cdot 3} +, \text{\&c.}$$

It has been shown in algebra (sect. 177) that the second member of this equation is the development of the function e^x, where e denotes the number 2·7182818, viz. the base of Napier's logarithms; therefore, if n be supposed to increase continually, the expression $\left(1 + \frac{x}{n}\right)^n$ will approach to e^x as its limit; and making $x = 1$, the limit of $\left(1 + \frac{1}{n}\right)^n = e = 2{\cdot}7182818$, a constant quantity.

4. Since the value of a function depends essentially on that of the variable, which is its basis, any change in the value of the latter will produce a corresponding change in the value of the former.

First, let the function be $u = x^2$, and let us suppose that the variable changes its value, being increased by a quantity h, and thereby becoming $x + h$; let u' denote the corresponding value of u, so that we have

$$u' = (x + h)^2 = x^2 + 2xh + h^2 = u + 2xh + h^2;$$

hence $u' - u = 2xh + h^2$.

It thus appears that, h denoting the increment of the variable x, the corresponding increment of the function, viz. $u' - u$, is $2xh + h^2$.

The algebraic expression for a ratio is a fraction whose numerator is the antecedent, and denominator the consequent. In the present case, the ratio of the increment of the function to that of its variable is

$$\frac{u' - u}{h} = 2x + h.$$

As another example, let the function be $u = x^3$; then, supposing, as before, that the variable x is increased by the quantity h, and, putting u' for the new value of the function, we have

$$u' = (x + h)^3 \begin{cases} = x^3 + 3x^2h + 3xh^2 + h^3 \\ = u + 3x^2h + 3xh^2 + h^3; \end{cases}$$

$$\frac{u' - u}{h} = 3x^2 + 3xh + h^2.$$

In this case we see that when x has increased to $x + h$, the function u has become

$$u + 3x^2h + 3xh^2 + h^3,$$

having received the increment $3x^2h + 3hx^2 + h^3$, a quantity composed of the integer powers of h. Farther, it appears that the expression for the ratio of the increments is

$$3x^2 + 3xh + h^2,$$

of which the first term $3x^2$ is entirely independent of the value of h, the increment of x.

When the function is $u = x^4$, we have, putting, as in the former examples, h for the increment of the variable, and u' for the new value of the function,

$$u' = u + 4x^3h + 6x^2h^2 + 4xh^3 + h^4,$$

$$\frac{u' - u}{h} = 4x^3 + 6x^2h + 4xh^2 + h^3.$$

From these examples it appears, that when x changes its value and becomes $x + h$, then the new value of the function

$u = x^2$ becomes $u' = u + 2xh + h^2$,
$u = x^3$ becomes $u' = u + 3x^2h + 3xh^2 + h^3$,
$u = x^4$ becomes $u' = u + 4x^3h + 6x^2h^2 + 4xh^3 + h^4$;

and in general that

$u = x^n$, any integer power of x, becomes
$u' = u + ph + qh^2 + rh^3 + sh^4 +$, &c.

the new value of the function being composed of a series of terms, the first of which is its original value, and the following terms, integer powers of the increment h, multiplied by p, q, r, &c. certain other functions of x, the forms of which depend on the original function, whence they have been derived.

Farther, it appears that

when $u = x^2$, then $\dfrac{u' - u}{h} = 2x + h$;

when $u = x^3$, $\dfrac{u' - u}{h} = 3x^2 + 3xh + h^2$;

when $u = x^4$, $\dfrac{u' - u}{h} = 4x^3 + 6x^2h + 4xh^2 + h^3$;

and, in general, that when $x = u^n$, n being any whole number, then

$$\frac{u' - u}{h} = p + qh + rh^2 + sh^3 +, \&c.$$

Thus it appears that the expression for $\dfrac{u' - u}{h}$, the ratio of the increment of the function x^n to that of its variable x, may be resolved into two parts, one, p, which is independent of the increment, and another, $qh + rh^2 + sh^3 +$, &c.; or

$$h\,(q + rh + sh^2 +, \&c.),$$

which, having h the increment as a factor, must decrease with it, and, by giving a sufficiently small value to h, may become less than any assignable quantity, so that the first term p is the limit of the ratio.

Let us consider the complex function

$$u = a + bx + cx^2.$$

When x becomes $x + h$, u becomes

$$\begin{aligned} u' &= a + b\,(x + h) + c\,(x + h)^2 \\ &= a + bx + cx^2 + (b + 2cx)\,h + ch^2, \end{aligned}$$

hence $u' - u = (b + 2cx)\,h + ch^2$,

$$\frac{u' - u}{h} = b + 2cx + ch.$$

In this case the limit of the ratio is $b + 2cx$. By a like examination of particular functions it will be found that they have all a common property, that is,

If u *be any function of a variable* x, *and if in that function* x *be supposed to change its value and become* x + h; *the corresponding new value of the function will be*

$$u' = u + ph + qh^2 + rh^3 +, \&c.$$

and the ratio of the increments of the function and its variable,

$$\frac{u' - u}{u} = p + qh + rh^2 +, \&c.;$$

an expression which, when h *is supposed to decrease continually, has for its limit the first term* p; *and this limit will be different for different functions, there being such a connection between the function and its limit, that the one may be found from the other.*

This property of the increments of a function and its variable suggests an important and extensive analytical theory, which will consist of two parts.

I. Any function of a variable quantity being proposed, to determine the limit of the ratio of the corresponding increments of the function and its variable.

II. On the other hand, having given the ratio of the increments, to find the function from which it has been derived.

These two inquiries constitute at bottom the *Direct and Inverse Method of Fluxions* of Newton, the *Differential and Integral Calculus* of Leibnitz, and the *Theory of Functions* of Lagrange. Our present subject is the direct method of fluxions, or its equivalent, the differential calculus.

5. We have seen (4), that by the transition of a function, for example, $u = x^2$, from one state of magnitude to another, by a change in the magnitude of its variable x, it acquires the new value $u' = u + 2xh + h^2$. The *whole difference* $u' - u$ between its new and first values is $2xh + h^2$. It is the first term of this difference, viz. $2xh$, that constitutes what is called the *differential* of the function from which it has been derived; and the determination of this first term for any function is the object of this first part of our calculus.

In like manner, in the function $u = x^3$, which, when x becomes $x + h$, changes to $u' = u + 3x^2h + 3xh^2 + h^3$, the whole difference between the two states of magnitude of the function is $3x^2h + 3xh^2 + h^3$, and its differential is $3x^2h$. And the whole difference between the first and succeeding value of the function $u = x^4$ is $4x^3h + 6x^2h^2 + 4xh^3 + h^4$, and its differential, is $4x^2h$. And, in general, whatever be the nature of the function u, if $x + h$ be substituted in it instead of x, and the expression thus formed be expanded into a series,

$$u + ph + qh^2 + rh^3 + sh^4, \&c.$$

the complete difference between the two states of the function is

$$ph + qh^2 + rh^3 + sh^4 +, \&c.$$

and its differential is the first term ph.

In conformity with this definition, the differential of the variable x itself will be its increment h, which, because of its use in generating the differential of the function, has been designated by a peculiar symbol, viz. dx: here the letter d is to be understood as a characteristic, not as a co-efficient. The letter d is also prefixed to the symbol for a function to denote its differential. Thus, supposing $u = x^2$, we have $du = 2xdx$, an expression which means that the differential of the function u is equal to the differential of the variable multiplied by $2x$ as a co-efficient; so also, if $u = x^3$, the equation $du = 3x^2dx$ means that the differential of u is equal to the differential of x multiplied by $3x^2$.

6. Since, when $u = x^2$, then $du = 2xdx$, this last expression may otherwise stand thus, $\frac{du}{dx} = 2x$; under this form $2x$ is the co-efficient in the expression for the differential of u, and it is on that account called the *differential co-efficient* of the function u or x^2. In like manner, when $u = x^3$, then $du = 3x^2dx$ and $\frac{du}{dx} = 3x^2$; in this case $3x^2$ is the differential co-efficient of the function $u = x^3$. The general symbol for the differential co-efficient of any function u is $\frac{du}{dx}$, and the new value of u being $u + ph + qh^2$ +, &c. we have $\frac{du}{dx} = p$, where p is some function of x, which depends on the form of the function u, and is deducible from it when its form is known.

To denote the differential of an expression formed in any way, we prefix the symbol d to the expression. Thus $d\{(a + x)(b^2 - x^2)\}$ denotes the differential of a function produced by multiplying the factors $a + x$ and $b^2 - x^2$, and $\frac{d\{(a + x)(b^2 - x^2)\}}{dx}$ serves to denote its differential co-efficient.

The definition which has been given of a differential suggests immediately this rule for finding the differential of a function of a single variable.

Substitute x + h *in the function instead of* x; *expand the expression thus formed into a series of terms composed of integer powers of* h, *and take the term which contains the first power of* h *for the differential, exchanging the letter* h *for the symbol* dx.

Thus, let the function be $u = ax + bx^2$, in which a and b are constants, then, putting $x + h$ for x, and u' for the new value of u, we have

$$u' \left\{ \begin{array}{l} = a(x + h) + b(x+h)^2 \\ = ax + bx^2 + (a + 2bx)h + bh^2 \\ = u + (a + 2bx)h + bh^2. \end{array} \right.$$

Here du, the differential of the function, is $(a + 2bx)h$, or $(a + 2bx)\,dx$, and $\frac{du}{dx} = a + 2bx$ the differential co-efficient.

7. The rule given in last article, for determining the differential of a function, supposes that we have methods by which any function may be expanded into a series of terms, into each of which some integer power of the increment h enters only as a factor. It is sufficient for our purpose, however, if we can find that term of the series which contains the simple power of h; and this can in general be found easier than the general development, which indeed may be the very thing to be investigated by the calculus. Now we have seen (4) that the co-efficient of this term is the expression for the limit of the ratio of the corresponding increments of a function and its variable, and the same quantity is the differential co-efficient of the function (6), therefore the determination of the differential of a function is the same thing as the determination of the limit of the ratio of the increments.

Direct Method.

Let the function be $u = \frac{a^2}{x}$; then $u' = \frac{a^2}{x + h}$, and

$$u' - u = \frac{a^2}{x + h} - \frac{a^2}{x} = \frac{-a^2h}{x(x + h)};$$

and the limit of the ratio of the increments is

$$\frac{u' - u}{h} = \frac{-a^2}{x(x + h)}.$$

Now, without expanding the expression for the limit, it is obvious that as h decreases, that expression approaches to $-\frac{a^2}{x^2}$, which is therefore $\frac{du}{dx}$, the differential co-efficient of the function; hence $du = -\frac{a^2\,dx}{x^2}$. In like manner, u being the general expression for any function, and $u' = u + ph + qh^2 +$, &c. its expanded value when $x + h$ is put instead of x, we have

$$\frac{u' - u}{h} = p + qh +, \&c.$$

$$\text{and limit of } \frac{u' - u}{h} = p = \frac{du}{dx}, \text{ and } du = pdx.$$

According to this view of the subject, *the differential calculus is the finding of the ratios of the simultaneous increments of a function and of the variable on which it depends.*

The process of calculation by which the differential of any function u is found, may be regarded as a particular operation performed on quantity, analogous to the elementary operations of algebra; and it may, like these, be distinguished by a particular name accordingly. The result of the process being the *differential*, the process itself is called *differentiation*, and to perform the process on a function is to *differentiate* the function.

8. It is material to observe, that the limit of the ratio of the increments of a function and its variable are the very same, whichever of the two be considered as a function of the other. Thus, u being a function of x, when x becomes $x + h$, u becomes $u + ph + qh^2 + rh^3 +$, &c. p, q, r, &c. being functions of x, deducible from the function u. Let us put

$$k = ph + qh^2 + rh^3 +, \&c.$$

so that the contemporaneous increments of x and u are h and k. Now, from the value of k, by the reversion of series (ALGEBRA, art. 163), we find

$$h = \frac{1}{p}\,k - \frac{q}{p^3}\,k^2 +, \&c.$$

So that, regarding x as a function of u, when u becomes $u + k$, x becomes

$$\frac{1}{p}\,k - \frac{q}{p^3}\,k^2 +, \&c.$$

and the general expression for the ratio of the increments is

$$\frac{h}{k} = \frac{1}{p} - \frac{q}{p^3}\,k +, \&c.$$

which has for its limit $\frac{1}{p}$, and the limit of the ratio $\frac{k}{h}$ is, as before, $= p$.

9. It is easy to see that two equal functions must have equal differentials; for whatever be the value of the va-

riable on which they depend, it must necessarily happen that the respective changes they receive in consequence of the change which is attributed to the variable must also be equal. Thus, if u and v be two functions, such, that $u = v$, whatever may be the value of x; and if, when x becomes $x + h$, then u becomes u', and v becomes v', we shall have $u' = v'$, and $u' - u = v' - v$, and

$$\frac{u' - u}{h} = \frac{v' - v}{h}.$$

If then p and q denote the limits of these ratios, $p = q$ and $pdx = qdx$, that is, $du = dv$.

From this it follows, that under whatever form a function appears, its differential is the very same quantity. For example, the differential of $x^3 + a^3$ will be identical with the differential of $(x + a)(x^2 - ax + a^2)$, its equal.

The converse of this proposition is not generally true, and we should be wrong in affirming that two equal differentials belong to equal functions. For, let $u = a + bx$ be a function of x, then, substituting $x + h$ for x, and putting u' for the new value of u, we have $u' = a + bx + bh = u + bh$, and $\frac{u' - u}{h} = b$.

We see here that the constant a does not enter into the limit of the ratio of the increments, which would therefore be the very same for the function $u = bx$; hence it follows that the differential bdx belongs alike to $a + bx$, and to bx. Thus it appears, that in differentiating any function whatever, all the constant quantities combined with it, either by addition or subtraction, disappear. With respect to those which are connected by multiplication and division, they enter the result as co-efficients.

10. The differential of any function of a variable x may be found by the general methods indicated in article 6; but it is convenient to have rules adapted to particular cases.

Let r and s be two functions of a variable x. It is proposed to investigate a rule for finding the differential of $u = rs$, their product.

Suppose that by the substitution of $x + h$ for x in the functions r and s, and their expansion, they become $r' = r + ph + qh^2 +$, &c. $s' = s + p'h + q'h^2 +$, &c.

In these expressions, p, q, &c. represent functions of x, derived from r; and p', q', &c. other functions of x derived from s. Corresponding to these let u' denote $r's'$, the new value of the product $rs = u$. By actual multiplication we find

$u' = r's' = rs + (rp' + sp)h + (rq + pp' + sq)h^2 +$, &c.

Hence, putting u for rs, also transposing and dividing by h, there is got

$$\frac{u' - u}{h} = rp' + sp + (rq' + pp' + sq)h +, \&c.$$

The terms rp' and sp in the second member of this equation are functions of x, which are independent of the function h; the following terms are all multiplied by h, therefore they decrease and vanish with it. So that

$$\text{limit of ratio } \frac{u' - u}{h} = rp' + sp.$$

$$\text{Now } p = \text{limit of } \frac{r' - r}{h}, \text{ and } q = \text{limit of } \frac{s' - s}{h}.$$

Instead of the limits of the ratios, let us put the differential co-efficients of the functions u, r, s (art. 6), and we find

$$\frac{du}{dx} = r\frac{ds}{dx} + s\frac{dr}{dx},$$

$$\text{and } du = rds + sdr.$$

Hence we have this rule, *To find the differential of the product of two functions, multiply the differential of each by the differential of the other function, and add the products.*

11. Since, when $u = rs$, we have $du = sdr + rds$, it follows that

$$\frac{du}{u} = \frac{dr}{r} + \frac{ds}{s}.$$

If we suppose $u = rtv$, the product of three factors, by putting $s = tv$, we have $u = rs$, and

$$\frac{du}{u} = \frac{dr}{r} + \frac{ds}{s};$$

but since $s = tv$, we have for the same reason

$$\frac{ds}{s} = \frac{dt}{t} + \frac{dv}{v};$$

$$\text{therefore } \frac{du}{u} = \frac{dr}{r} + \frac{dt}{t} + \frac{dv}{v}.$$

By writing the product rst instead of u, there is got, after proper reduction,

$$du = tvdr + rvdt + rtdv.$$

In general, *If a function be the product of any number of functions of a variable, its differential is the sum of the products obtained by multiplying the differential of each by the product of all the other functions.*

The same rule may also be briefly expressed in symbols, thus: whatever be the number of functions r, s, t, v,

$$d\,(rstv) = rstv\left\{\frac{dr}{r} + \frac{ds}{s} + \frac{dt}{t} + \frac{dv}{v}\right\}.$$

12. To find the differential of a fraction whose numerator and denominator are functions of a variable x; let $u = \frac{r}{s}$, then $r = us$, and

$$dr = uds + sdu,$$

and, putting for u its value $\frac{r}{s}$,

$$dr = \frac{rds}{s} + sdu;$$

$$\text{therefore, } du = \frac{sdr - rds}{s^2}.$$

Hence we have this rule: *To find the differential of a fraction; from the differential of the numerator multiplied by the denominator subtract the differential of the denominator multiplied by the numerator, and divide by the square of the denominator.*

The rule for the differential of $u = \frac{r}{s}$ may be also symmetrically expressed thus:

$$\frac{du}{u} = \frac{dr}{r} - \frac{ds}{s};$$

and in general, if $u = \frac{rst}{vy}$, then

$$\frac{du}{u} = \frac{dr}{r} + \frac{ds}{s} + \frac{dt}{t} - \frac{dv}{v} - \frac{dy}{y}.$$

For, by what has been shown, it appears that when $u = \frac{rst}{vy}$, then

$$\frac{du}{u} = \frac{d(rst)}{rst} - \frac{d(vy)}{vy}.$$

$$\text{Now } \frac{d(rst)}{rst} = \frac{dr}{r} + \frac{ds}{s} + \frac{dt}{t},$$

$$\text{and } \frac{d(vy)}{vy} = \frac{dv}{v} + \frac{dy}{y};$$

therefore, $\frac{du}{u} = \frac{dr}{r} + \frac{ds}{s} + \frac{dt}{t} - \frac{dv}{v} - \frac{dy}{y}$.

It also follows, from what has been shown, that if the numerator of a fraction consist of any number of factors r, s, t, and the denominator of any number v, y, then

$$d\left\{\frac{rst}{vy}\right\} = \frac{rst}{vy}\left\{\frac{dr}{r} + \frac{ds}{s} + \frac{dt}{t} - \frac{dv}{v} - \frac{dy}{y}\right\}.$$

13. We shall next investigate a rule for the differential of any power of a function y, which may be either itself an independent variable, or else some function of another variable.

First, let $u = y^n$, n being any whole number. The function may be put under this form,

$$u = y \cdot y \cdot y \cdot y \ldots \text{ to } n \text{ terms,}$$

and then (11) we have

$$\frac{du}{u} = \frac{dy}{y} + \frac{dy}{y} + \frac{dy}{y} + \frac{dy}{y} \ldots \text{ to } n \text{ terms;}$$

that is, $\frac{du}{u} = \frac{ndy}{y}$,

$$\text{and } du = \frac{ndy}{y} u = ny^{n-1}\,dy.$$

Next, let us suppose that the function has a fractional exponent, and that $u = y^{\frac{m}{n}}$, then $u^n = y^m$,

$$\text{and } nu^{n-1}\,du = my^{m-1}\,dy, \text{ by art. 9,}$$

$$\text{and } du = \frac{m}{n}\,\frac{y^{m-1}}{u^{n-1}}\,dy;$$

$$\text{but } u = y^{\frac{m}{n}} \text{ and } u^{n-1} = y^{m - \frac{m}{n}};$$

$$\text{therefore } \frac{y^{m-1}}{u^{n-1}} = y^{\frac{m}{n} - 1},$$

$$\text{and } du = \frac{m}{n}\,y^{\frac{m}{n} - 1}.$$

Lastly, let us suppose n to be a negative whole number or fraction, so that $u = \frac{1}{y^n}$. In this case we may apply the rule for a fraction (12); and observing that the numerator here is a constant, of which the differential must be accounted $= 0$, we have

$$du = -\frac{ny^{n-1}dy}{y^{2n}} = -ny^{-n-1}dy;$$

thus it appears, that whether n be whole or fractional, positive or negative,

$$d(y^n) = ny^{n-1}dy.$$

Hence this rule: *To differentiate any power of a function, multiply it by the exponent, diminish the exponent by an unit, and multiply by the differential of the variable.*

If the function have a co-efficient, the differential must be multiplied by that co-efficient. Thus

$$d(ax^n) = nax^{n-1}\,dx.$$

The determination of the differential of a power of a variable might have been shortened by assuming the truth of the binomial theorem, as found in our article ALGEBRA, art. 160, 161. That theorem however may be derived from the differential calculus, and we shall give its investigation as one of its applications.

It frequently happens that the differential of $\sqrt{y} = y^{\frac{1}{2}}$, the square root of a function, is to be found; therefore a rule for that case will be convenient. By the general rule for a power,

$$d(y^{\frac{1}{2}}) = \tfrac{1}{2}y^{\frac{1}{2}-1}dy = \tfrac{1}{2}y^{-\frac{1}{2}}dy,$$

$$\text{that is, } d(\sqrt{y}) = \frac{dy}{2\sqrt{y}}.$$

Hence it appears that *the differential of the square root of a function is the differential of the function divided by twice its square root.*

14. Let y be a function of a variable x, and let u be a function of y; it is proposed to investigate a rule for finding the differential of u relatively to x.

Suppose x to change its value and become $x + h$, then y becomes $y' = y + ph + qh^2 + rh^3 +$, &c.; or, putting $ph + qh^2 + rh^3 +$, &c. $= k$, y becomes $y + k$. But u being a function of y, when y becomes $y + k$, then u becomes $u' = u + p'k + q'k^2 + r'k^3 +$, &c.; here p', q', r', &c. denote certain functions of y, which are independent of k and also of h. Hence, by substituting for k in this last series, its value $ph + qh^2 +$, &c., it appears that when x becomes $x + h$, u becomes

$$u' = u + p'ph + (p'q + q'p^2)\,h^2 +, \&c.$$

$$\text{and hence } \frac{u' - u}{h} = p'p + (p'q + q'p^2)h +, \&c.$$

Suppose now h to decrease continually, we have

$$\text{limit of } \frac{u' - u}{h} = p'p.$$

Now, y being a function of x, $p = \frac{dy}{dx}$, and u being considered as a function of y, $p' = \frac{du}{dy}$; but if we consider u as a function of x, then

$$\frac{du}{dx} = \text{limit } \frac{u' - u}{h} = p'p.$$

Hence it follows that

$$\frac{du}{dx} = \frac{du}{dy} \times \frac{dy}{dx},$$

$$\text{and } du = \left(\frac{du}{dy} \times \frac{dy}{dx}\right)dx.$$

Hence this rule: To find, relatively to x, the differential of u, a function of y, the quantity y being a function of x, *Find the differential co-efficient of* u *considered as a function of* y *only, and the differential co-efficient of* y *considered as a function of* x; *multiply the product of these co-efficients by the differential of* x, *and the result is the differential of* u.

It has been found that

$$\frac{du}{dy} \times \frac{dy}{dx} = \frac{du}{dx};$$

Now if we suppose that $u = x$, then this expression becomes

$$\frac{dx}{dy} \times \frac{dy}{dx} = \frac{dx}{dx} = 1;$$

and hence it appears that

$$\frac{dx}{dy} = \frac{1}{\frac{dy}{dx}}.$$

This shows that the differential co-efficient of x considered as a function of y, is the reciprocal of the differential co-efficient of y considered as a function of x, a conclusion which may also be deduced from art. 8.

15. Let v, y, z be functions of a variable x, and let it be proposed to find the differential of

$$u = a + bv + cy - ez,$$

where a, b, c, e, denote constants.

Let us suppose that when x becomes $x + h$, then

$$v \text{ becomes } v + ph + qh^2 +, \&c.$$
$$y \text{ becomes } y + p'h + q'h^2 +, \&c.$$
$$z \text{ becomes } z + p''h + q''h^2 +, \&c.$$

Let u' be the corresponding value of u, so that

$$u = \begin{cases} a + bv + cy - ez \\ + (bp + cp' - ep'')h \\ + (bq + cq' - eq'')h^2 \\ +, \&c. \end{cases}$$

Hence, putting for the first term of the second member of the equation its value u, and transposing and dividing by h, we get

$$\frac{u' - u}{h} = bp + cp' - ep'' + (bq + cq' - eq'')h, \&c.$$

And passing to the limits, observing that the limit of $\frac{u' - u}{h}$ is the differential co-efficient of u, also that p, p', and p'' are the differential co-efficients of v, y, and z respectively, we get

$$\frac{du}{dx} = \frac{bdv}{dx} + \frac{cdy}{dx} - \frac{edz}{dx},$$

$$\text{and } du = bdv + cdy - edz.$$

From this it appears that *the differential of a function made up of others simply by addition and subtraction is composed in like manner of the differentials of the several terms, each with the sign of the function from which it was derived; the differential of a constant being reckoned* = 0.

16. These rules are sufficient for the differentiation of any explicit algebraic function, and we shall now give examples.

1. Let $u = ax^5$; this is a particular case of the general function $u = ax^n$; therefore, by the rule (13) $du = 5ax^4dx$.

2. Let $u = \frac{a}{x^5} = ax^{-5}$; then $du = -5\,ax^{-6}\,dx = \frac{-5adx}{x^6}$.

3. Let $u = \sqrt{x^3} = x^{\frac{3}{2}}$; in this case $du = \frac{3}{2}x^{\frac{1}{2}}dx = \frac{3}{2}\,dx\sqrt{x}$.

4. Let $u = ax^3 + bx^2 + cx + e$;
then $du = 3ax^2dx + 2bxdx + cdx$,
or $du = (3ax^2 + 2bx + c)\,dx$.

Here the constant e, which is a term of the function, has disappeared by the differentiation.

5. Let $u = (a + bx^n)^p$; we may put $y = a + bx^n$, and then $u = y^p$; and $du = py^{p-1}dy$.

Now $y^{p-1} = (a + bx^n)^{p-1}$, and $dy = bnx^{n-1}dx$;

therefore $du = bnp\,(a + bx^n)^{p-1}\,x^{n-1}dx$.

We might have dispensed with using the symbol y, and regarded $a + bx^n$ as a single function, and u as a power of that function, and found the differential by the rule of art. 13.

As an example of the rule of art. 10, for the product of two functions,

6. Let $u = x^3\,(a + x)^2$;
put $p = x^3$, and $q = (a + x)^2$; then $u = pq$,
and $du = qdp + pdq$.

Now $dp = 3x^2dx$, and $dq = 2\,(a + x)\,dx$;
therefore $du = 3x^2\,(a + x)^2\,dx + 2x^3\,(a + x)\,dx$
$= x^2\,(a + x)\,(3a + 5x)\,dx$.

In practice, the introduction of the symbols p and q may be omitted.

7. Let $u = x\,(1 + x)\,(1 + x^2)$. In this case, u is the product of three functions; therefore, by the rule of art. 11, $du = (1 + x)\,(1 + x^2)\,dx + x\,(1 + x^2)\,dx + 2x^2\,(1 + x)\,dx$. This, when abbreviated by multiplication, becomes $du = (1 + 2x + 3x^2 + 4x^3)\,dx$.

We might have proceeded otherwise by the rule

$$d\,(rst) = rst\left\{\frac{dr}{r} + \frac{ds}{s} + \frac{dt}{t}\right\};$$

accordingly, we would have had

$$du = x\,(1 + x)\,(1 + x^2)\left\{\frac{dx}{x} + \frac{dx}{1 + x} + \frac{2xdx}{1 + x^2}\right\},$$

an expression reducible to the former.

8. As an example of a fractional function, let $u = \frac{x}{1 + x^2}$; we have, following the rule of art. 12,

$$du = \frac{(1 + x^2)\,dx - 2\,x^2dx}{(1 + x^2)^2} = \frac{(1 - x^2)dx}{(1 + x^2)^2}.$$

9. Again, let $u = \frac{x^3 + x}{x^4 - x^2 + 1} = \frac{x(x^2 + 1)}{x^4 - x^2 + 1}$; this may exemplify the rule

$$d\left(\frac{rs}{t}\right) = \frac{rs}{t}\left\{\frac{dr}{r} + \frac{ds}{s} - \frac{dt}{t}\right\}.$$

Accordingly, making $x = r$, $x^2 + 1 = s$, $x^4 - x^2 + 1 = t$, we have

$$du = \frac{x^3 + x}{x^4 - x^2 + 1}\left\{\frac{dx}{x} + \frac{2xdx}{1 + x^2} - \frac{(4x^3 - 2x)\,dx}{x^4 - x^2 + 1}\right\}.$$

This by reduction becomes

$$du = \frac{-\{x^6 + 4x^4 - 4x^2 - 1\}dx}{(x^4 - x^2 + 1)^2}.$$

10. As an example of the rule in art. 14, let $u = 3y^2$, and $y = x^3 + ax$; then

$$\frac{du}{dy} = 6y, \quad \frac{dy}{dx} = 3x^2 + a;$$

$$\frac{du}{dy}\cdot\frac{dy}{dx} = 6y\,(3x^2 + a) = 18\,x^2y + 6ay,$$

$$\text{and } du = \frac{du}{dy}\cdot\frac{dy}{dx}\cdot dx = 18x^2ydx + 6aydx.$$

We may in such an example proceed otherwise, thus; because $u = 3y^2$, $du = 6ydy$;
and since $y = x^3 + ax$, $dy = 3x^2 + adx$,
substitute this value of dy in the expression for du, and it becomes

$$du = 18x^2y + 6aydx,$$

the same as before.

17. The subjects which are to follow require the application of the binomial theorem, we shall therefore give its investigation, as the first application of the calculus.

Supposing n to be any number whatever, whole or fractional, positive or negative, it is easy to infer, from the consideration of particular cases, that

$$(1 + x)^n = 1 + \mathrm{A}x + \mathrm{B}x^2 + \mathrm{C}x^3 + \mathrm{D}x^4 +, \&c.,$$

the co-efficients A, B, C, &c., in the series being numbers altogether independent of x, and deducible from the index n alone. The expression $(1 + x)^n$ and its development being equal for all values of x, they form an identical equation, and must have equal differentials, hence (art. 9) we have, taking the differential of each term,

$$n(1 + x)^{n-1}\,dx = \mathrm{A}dx + 2\mathrm{B}xdx + 3\mathrm{C}x^2dx + 4\mathrm{D}x^3dx +, \&c.$$

Leaving now dx out of each term, and multiplying both sides by $1 + x$, the result is

$$n(1 + x)^n = \mathrm{A} + (\mathrm{A} + 2\mathrm{B})x + (2\mathrm{B} + 3\mathrm{C})x^2 + (3\mathrm{C} + 4\mathrm{D})x^3 +, \&c.$$

But from the assumed series we have

$$n(1 + x)^n = n + n\mathrm{A}x + n\mathrm{B}x^2 + n\mathrm{C}x^3 +, \&c.$$

Now the terms of these two expansions of $n(1 + x)^n$ must be identical; therefore

$$\left.\begin{aligned} \mathrm{A} &= n, \\ \mathrm{A} + 2\mathrm{B} &= n\mathrm{A}, \\ 2\mathrm{B} + 3\mathrm{C} &= n\mathrm{B}, \\ 3\mathrm{C} + 4\mathrm{D} &= n\mathrm{D}, \\ &\&c. \end{aligned}\right\}\text{ and hence }\left\{\begin{aligned} \mathrm{A} &= n; \\ \mathrm{B} &= \frac{(n-1)}{2}\mathrm{A}; \\ \mathrm{C} &= \frac{n-2}{3}\mathrm{B}; \\ \mathrm{D} &= \frac{n-3}{4}\mathrm{C}; \\ &\&c. \end{aligned}\right.$$

By substituting for A its value in B, and for B the resulting value in C, and so on, there is found

$$(1+x)^n=1+\frac{n}{1}x+\frac{n(n-1)}{1\,.\,2}x^2+\frac{n(n-1)(n-2)}{1\,.\,2\,.\,3}x^3+\text{\&c.}$$

and again, by putting $\frac{v}{a}$ instead of x, and multiplying both sides of the equation by a^n, we get

$$(a+x)^n=a^n+\frac{n}{1}a^{n-1}x+\frac{n(n-1)}{1\,.\,2}a^{n-2}x^2$$
$$+\frac{n(n-1)(n-2)}{1\,.\,2\,.\,3}a^{n-3}x^3+,\text{\&c.}$$

18. In the investigation of the binomial theorem we have employed a principle of analysis of continual use in the calculus, namely, that in such an equation as this (called an *Identical Equation*),

$a+bx+cx^2+ex^3+$&c., $=A+Bx+Cx^2+Ex^3+$ &c.(1.)

in which a, b, c, &c., A, B, C, &c. are constants, and x is variable; in order that the equation may hold universally true, it is necessary that $a=A$, $b=B$, $c=C$, $e=E$, &c. For since x is indeterminate, we may suppose it to decrease until it vanish; then all the terms into which it enters also vanish, and we have $a=A$; therefore, leaving these equal terms out of both sides of (1), and dividing all the remaining terms by x, we get

$b+cx+ex^2+$, &c., $=B+cx+Ex^2+$, &c. (2.)

By proceeding with this equation as with the former, we obtain $b=B$, $c=C$, $e=E$, &c., and so on.

19. We come now to the investigation of the differentials of transcendental functions of a variable, and begin with the exponential function $u=a^x$, the exponent x being variable, and the quantity a constant. Assuming that when x becomes $x+h$, u becomes u', we have

$$u=a^x,\quad u'=a^{x+h}=a^x\ a^h;$$

therefore, $u'-u=a^x\ a^h-a^x=a^x(a^h-1)$;

$$\text{and } \frac{u'-u}{h}=a^x\frac{a^h-1}{h}.$$

The determination of the limit of the ratio of the increments requires that we determine the limit to which the value of the fraction $\frac{a^h-1}{h}$ tends when h is supposed to decrease continually. Let us put $a=1+c$; by the binomial theorem (art. 17),

$$a^h=(1+c)^h=1+hc+\frac{h(h-1)}{1\,.\,2}c^2+\frac{h(h-1)(h-2)}{1\,.\,2\,.\,3}c^3+\text{\&c.}$$

$$\text{therefore, } \frac{ah-1}{h}=c+\frac{h-1}{2}c^2+\frac{(h-1)(h-2)}{2\,.\,3}c^3+\text{\&c.}$$

Now h being supposed to decrease continually, the second side of this formula manifestly approaches to

$$c-\tfrac{1}{2}c^2+\frac{-1\,.-2}{2\,.\,3}c^3+\frac{-1\,.-2\,.-3}{2\,.\,3\,.\,4}c^4+\text{\&c.}$$

that is, to $c-\frac{1}{2}c^2+\frac{1}{3}c^3-\frac{1}{4}c^4+$, &c.

$=(a-1)-\frac{1}{2}(a-1)^2+\frac{1}{3}(a-1)^3-\frac{1}{4}(a-1)^4+$, &c.

Now it has been shown in ALGEBRA (art. 173), and will be proved in the sequel, that this series expresses Napier's logarithm of the number a. Therefore,

$$\text{limit of } \frac{a\ -1}{h}=\text{Nap. log } a,$$

$$\text{and hence, } \frac{du}{dx}=\text{limit } \frac{u'-u}{h}=a^x(\text{Nap. log } a),$$

$$\text{and } du=(\text{Nap. log } a)\ a^x dx.$$

We have now this rule for differentiating a function which is a variable power of a constant quantity.

Multiply the function by the differential of the variable index, and by Napier's log. of the constant quantity.

Note.—The logarithm of a number a, in any system whatever, will in what follows be expressed by the abbreviation log a; but when the system is that of Napier, we shall denote it thus, l. a.

20. To find the differential of the transcendental $u=\log x$, the base of the system being a. By the definition of a logarithm (ALGEBRA, art. 165),

$$x=a^u,$$

and, supposing that x becomes $x+h$, and that u becomes u',

$$x+h=a^{u'};$$

therefore, $h=a^{u'}-a^u=a^u(a^{u'-u}-1)=x(a^{u'-n}-1)$;

and hence, making $k=u'-u$,

$$\frac{h}{u'-u}=\frac{x(a^k-1)}{k};$$

$$\text{and } \frac{u'-u}{h}=\frac{1}{x}\cdot\frac{k}{a^k-1}.$$

Passing now to the limits of the two sides of the equation, and observing (as was proved in last article) that k being supposed to decrease continually,

$$\text{limit of } \frac{k}{a^k-1}=\frac{1}{\text{l.}\,a},$$

$$\text{we have } \frac{du}{dx}=\frac{1}{\text{l.}\,a}\cdot\frac{1}{x}.$$

Let M denote the constant factor, viz. the reciprocal of Napier's logarithm of the base of the system of logarithms, which is the modulus of the system (ALGEBRA, art. 172), and we have

$$du=\frac{Mdx}{x};$$

That is, *The differential of the logarithm of a number is found by multiplying the differential of the number by the modulus of the system and dividing by the number.*

Note.—In Napier's system $M=1$.

21. The differentials of the trigonometrical functions sin x and cos x are next to be investigated.

Let $u=\sin x$, and $u'=\sin(x+h)$; then (ALGEBRA, 240),

$u'-u=\sin(x+h)-\sin x=2\cos(x+\frac{1}{2}h)\sin\frac{1}{2}h$,

$$\text{and } \frac{u'-u}{h}=\cos(x+\tfrac{1}{2}h)\frac{\sin.\frac{1}{2}h}{\frac{1}{2}h}.$$

Observing now that h being understood to decrease continually until it vanish, the limit of $\cos(x+\frac{1}{2}h)$ is $\cos x$, and the limit of $\frac{\sin\frac{1}{2}h}{\frac{1}{2}h}=1$ (ALGEBRA, 266), we have

$$\frac{du}{dx}=\text{limit } \frac{u'-u}{h}=\cos x;$$

$$\text{and } du=dx\cos x.$$

Next let $u=\cos x$, and $u'=\cos(x+h)$ we have now

$u'-u=\cos(x+h)-\cos x=-2\sin(x+\frac{1}{2}h)\sin\frac{1}{2}h$;

$$\frac{u'-u}{h}=-\sin(x+\tfrac{1}{2}h)\frac{\sin\frac{1}{2}h}{\frac{1}{2}h}.$$

Passing now to the limits by supposing h to decrease continually,

$$\frac{du}{dx}=\text{limit } \frac{u'-u}{h}=-\sin x;$$

$$\text{and } du=-dx\sin x.$$

Hence it appears that *The differential of the sine of an arc is the product of the differential of the arc and its cosine:*

and that the differential of the cosine is the product of the differential of the arc and its sine with the sign — prefixed.

Note.—The negative sign indicates, that while the arc increases the cosine decreases when it is positive.

The differential of the cosine might have been found otherwise, by regarding it as a function of the sine. Thus, putting v for the sine, and y for the cosine; because $y^2 = 1 - v^2$, by differentiating, $ydy = -vdv$; now x being the arc, $dv = ydx$; therefore $ydy = -vydx$, and $dy = -vdx$.

22. The functions $u = \tan x, u = \cot x$, &c. may be considered as formed from the elementary functions $\sin x$ and $\cos x$.

(1.) Let $u = \tan x = \dfrac{\sin x}{\cos x}$, then (art. 12 and 20),

$$du = \frac{d(\sin x)\cos x - d(\cos x)\sin x}{\cos^2 x}$$

$$= \frac{(\cos^2 x + \sin x^2)dx}{\cos^2 x} = \frac{dx}{\cos^2 x}.$$

Hence, again, $du = dx \sec^2 x = dx(1 + \tan^2 x)$.

(2.) In the same way, if $u = \cot x$, we find

$$du = \frac{-dx}{\sin x^2} = -dx \operatorname{cosec}^2 x = -dx(1 + \cot^2 x).$$

(3.) Let $u = \sec x = \dfrac{1}{\cos x}$; then

$$du = \frac{dx \sin x}{\cos^2 x} = dx \tan x \sec x.$$

(4.) Let $u = \operatorname{cosec} x = \dfrac{1}{\sin x}$;

$$du = -\frac{dx \cos x}{\sin^2 x} = dx \cot x \operatorname{cosec} x.$$

23. Corresponding to the direct functions

$u = \sin x$, $u = \cos x$, &c.

there are the reverse functions,

$u = \text{arc}(\sin = x)$, $u = \text{arc}(\cos x)$, &c.

The first, viz. the arc whose sine is x, is sometimes by British writers expressed thus; $u = \sin^{-1} x$; and the second, the arc whose cosine is x, thus; $u = \cos x^{-1}$.

(1.) Let $u = \text{arc}(\sin = x) = \sin^{-1} x$;

then $x = \sin u$; and $dx = du \cos u = du\sqrt{1 - x^2}$;

$$\text{and } du = \frac{dx}{\sqrt{1 - x^2}}.$$

(2.) Let $u = \text{arc}(\cos = x) = \cos^{-1} x$:

then $x = \cos u$; and $dx = -du \sin u = -du\sqrt{1 - x^2}$;

$$\text{and } du = \frac{-dx}{\sqrt{1 - x^2}}.$$

(3.) Let $u = \text{arc}(\tan = x) = \tan^{-1} x$:

then $x = \tan u$ and $dx = du(1 + x^2)$;

$$\text{and } du = \frac{dx}{1 + x^2}.$$

(4.) Let $u = \text{arc}(\cot = x) = \cot^{-1} x$;

then $x = \cot u$ and $dx = -du(1 + u^2)$,

$$\text{and } du = \frac{-dx}{1 + x^2}.$$

(5.) Let $u = \text{arc}(\sec = x) = \sec^{-1} x$;

then $x = \sec u$; and $dx = du \sec u \tan u = du\, x\sqrt{x^2 - 1}$,

$$\text{and } du = \frac{dx}{x\sqrt{x^2 - 1}}.$$

(6.) Let $u = \text{arc}(\operatorname{cosec} = x) = \operatorname{cosec}^{-1} x$, then, proceeding as in the foregoing examples, we find

$$du = \frac{-dx}{x\sqrt{x^2 - 1}}.$$

24. Having now found rules for the differentiation of the elementary transcendentals and trigonometrical functions, we proceed to exemplify their application to the differentiation of complex functions.

(1.) Let the function be $u = x^y$, that is a variable x raised to a power y, a function of the variable.

By the theory of logarithms $\text{l.}\, u = y\, \text{l.}\, x$.

Put $v = \text{l.}\, u$ and $z = \text{l.}\, x$; then $v = yz$;

and $dv = ydz + zdy$ (art. 10).

$$\text{Now } dv = d(\text{l.}\, u) = \frac{du}{u}; \text{ and } dz = d(\text{l.}\, x) = \frac{dx}{x}\ (20);$$

$$\text{therefore, } \frac{du}{u} = \frac{ydx}{x} + \text{l.}\, x \,.\, dy,$$

$$\text{and } du \begin{cases} = u\left\{\dfrac{y}{x}dx + \text{l.}\, x \,.\, dy\right\} \\ = x^y\left\{\dfrac{y}{x}dx + \text{l.}\, x \,.\, dy\right\} \\ = x^{y-1}\, ydx + x^y\, \text{l.}\, x \,.\, dy. \end{cases}$$

(2.) If $u = x^x$, then, by last example,

$$du = x^x\left\{1 + \text{l.}\, x\right\} dx.$$

(3.) Let $u = a^{b^x}$; put $b^x = y$, then $u = a^y$,

and $du = \text{l.}\, a\, a^y dy$, also $dy = \text{l.}\, b \,.\, b^x\, dx$ (19);

therefore $du = \text{l.}\, a \,.\, \text{l.}\, b \,.\, a^{b^x}\, dx$.

In the following examples we shall suppose the logarithms to be those of Napier's system.

(4.) Let $u = \text{l.}\left\{\dfrac{x}{\sqrt{a^2 + x^2}}\right\}$. Making $\dfrac{x}{\sqrt{a^2 + x^2}} = z$,

we have $du = \dfrac{dz}{z}$; but

$$dz = \frac{dx\sqrt{a^2 + x^2} - \dfrac{x^2 dx}{\sqrt{a^2 + x^2}}}{a^2 + x^2} = \frac{a^2 dx}{(a^2 + x^2)^{\frac{3}{2}}};$$

$$\text{therefore } du = \frac{a^2 dx}{x(a^2 + x^2)}.$$

(5.) Let $u = \text{l.}\left\{\dfrac{\sqrt{1 + x} + \sqrt{1 - x}}{\sqrt{1 + x} - \sqrt{1 - x}}\right\}$;

put $y = \sqrt{1 + x} + \sqrt{1 - x}$, $z = \sqrt{1 + x} - \sqrt{1 - x}$;

then $u = \text{l.}\left(\dfrac{y}{z}\right) = \text{l.}\,(y) - \text{l.}\,(z)$;

$$\text{and } du = \frac{dy}{y} - \frac{dz}{z}.$$

$$\text{Now } dy = \frac{dx}{2\sqrt{1 + x}} - \frac{dx}{2\sqrt{1 - x}}$$

$$= \frac{-dx}{2\sqrt{1 - x^2}}\left\{\sqrt{1 + x} - \sqrt{1 - x}\right\} = \frac{-zdx}{2\sqrt{1 - x^2}},$$

$$\text{and } dz = \frac{dx}{2\sqrt{1 + x}} + \frac{x}{2\sqrt{1 - x}}$$

$$= \frac{dx}{2\sqrt{1 - x^2}}\left\{\sqrt{1 + x} + \sqrt{1 - x}\right\} = \frac{ydx}{2\sqrt{1 - x^2}};$$

$$\text{therefore } \frac{dy}{y} - \frac{dz}{z} = \frac{-2dx}{2y\sqrt{1 - x^2}} - \frac{ydx}{2z\sqrt{1 - x^2}}$$

$$= \frac{-(y^2 + z^2)dx}{2yz\sqrt{1 - x^2}};$$

and observing that

$$y^2 + z^2 = u, \quad yz = 2x,$$

we find at last $du = \frac{-dx}{x\sqrt{1 - x^2}}$.

In the next two examples we shall merely put down the results

(6.) $$u = \text{l.}\left\{x - \sqrt{1 + x^2}\right\}$$

$$du = \frac{dx}{\sqrt{1 + x^2}},$$

(7.) $$u = \text{l}\cdot\left\{\frac{\sqrt{1 + x^2} + x}{\sqrt{1 + x^2} - x}\right\}$$

$$du = \frac{dx}{\sqrt{1 + x^2}}.$$

25. As examples combining logarithmic and angular functions:

(1.) Let $u = \text{l. sin } n$;

then $du = \frac{dx \cos x}{\sin x} = dx \tan x$.

(2.) Let $u = \text{l. } (\tan x)$;

$$du \begin{cases} = \dfrac{dx \sec^2 x}{\tan x} = \dfrac{dx}{\sin x \cos x} \\ = \dfrac{2dx}{\sin 2x}. \end{cases}$$

26. As examples of complex angular functions:

(1.) Let $u = \tan^{-1} x$; that is, let u be the arc whose tangent is x, and let $z = \cos nu \cos^n u$.

It is proposed to find the differential co-efficient $\frac{dz}{dx}$.

In the first place, $du = \frac{dx}{\sec^2 u} = dx \cos^2 u$,

$$dz \begin{cases} = -ndu\,(\sin nu \cos^n u + \cos nu \sin u \cos^{n-1} u) \\ = -ndu \cos^{n-1} u\,(\sin nu \cos u + \cos nu \sin u) \\ = -ndu \cos^{n-1} u \sin (n + 1)\,u, \end{cases}$$

and $\frac{dz}{dx} = -n \sin (n + 1)\,u \cos^{n+1} u$.

(2.) Next, u being the same function of x as before,

let $z = \sin nu \cos^n u$,

to find the differential co-efficient $\frac{du}{dx}$.

In this case,

$$dz \begin{cases} = ndu\,(\cos nu \cos^n u - \sin nu \sin u \cos^{n-1} u) \\ = ndu \cos^{n-1} u\,(\cos nu \cos u - \sin nu \sin u) \\ = ndu \cos^{n-1} u \cos (n + 1)\,u, \end{cases}$$

and $\frac{dz}{dx} = n \cos (n + 1)\,u \cos^{n+1} u$.

Successive Differentiations.

27. A function of a variable, when differentiated, produces a new function, viz. its differential co-efficient. This in its turn may be differentiated, and there will be produced another differential co-efficient, which will stand in the same relation to the former as that did to the original function. By another differentiation, a third differential co-efficient may be formed; and so on continually, unless some differential co-efficient come out $= 0$.

For example, from the function $u = x^n$, we deduce $\frac{du}{dx} = n\,x^{n-1}$: putting now $p = nx^{n-1}$, we hence derive the differential co-efficient $\frac{dp}{dx} = n\,(n-1)\,x^{n-2}$; and putting $q = n(n-1)x^{n-2}$, we find $\frac{dq}{dx} = n(n-1)(n-2)x^{n-3}$. We may proceed in this way, until the result of a differentiation be a constant, and then the process will stop; but in some cases it may be continued indefinitely.

There is an appropriate notation to express the relation in which the successive differentials, p, q, &c. stand to the original function u, from which they have been derived: since

$$p = \frac{du}{dx}, \text{ and } q = \frac{dp}{dx}, \text{ therefore } q = \frac{d\left(\frac{du}{dx}\right)}{dx}:$$

The symbol $d\left(\frac{du}{dx}\right)$ will be more simply expressed by $d^2u\,.\,dx$; and thus we have

$$p = \frac{du}{dx},\; q = \frac{dp}{dx} = \frac{d^2u}{dx^2};$$

so that by the expression $q = \frac{d^2u}{dx^2}$, it is to be understood that q is the result of two differentiations performed on the function u, the differential of the variable, viz. dx, being considered as constant.

From the function q we may now deduce

$$r = \frac{dq}{dx} = \frac{d^3u}{dx^3},$$

and so on continually; but the different import of the characters d^3u and dx^3 must be carefully attended to; the former implies that the operation of differentiation has been performed three times on the function u, and the latter denotes the third power of dx. The combination of the two, $\frac{d^3u}{dx^3}$, expresses the function that results from the three differentiations, in each of which the factor dx has been left out, and the final result divided by its third power, or, if retained, that it has been regarded as constant.

(1.) As a particular case of the function $u = ax^n$, let $u = ax^5$;

$$\text{then } \frac{du}{dx} = 5ax^4, \quad \frac{d^2u}{dx^2} = 4{\cdot}5ax^3,$$

$$\frac{d^3u}{dx^3} = 3{\cdot}4{\cdot}5ax^2, \quad \frac{d^4u}{dx^4} = 2{\cdot}3{\cdot}4{\cdot}5ax,$$

$$\frac{d^5u}{d^5x} = 2{\cdot}3{\cdot}4{\cdot}5a.$$

In this example we have come to a differential co-efficient which is a constant, and the series stops; but if the index of the power x^n be a fraction or negative, the series may be continued indefinitely.

The expression $\frac{du}{dx}$ is called the *first* differential co-efficient of the function u, or the differential co-efficient of the *first order*; those which follow are called the *second*, *third*, &c. or the differential co-efficients of the *second*, *third*, &c. orders.

In the case of the function $u = x^5$, writers on the calculus of fluxions call $du = 5x^4dx$ the *first* fluxion of the function; $d^2u = 20x^3dx^2$ its *second* fluxion; $d^3u = 60x^2dx^3$ its *third* fluxion; and so on, the terms of the series constituting the different *orders* of fluxions.

Other examples of successive differentiation:

(2.) Let $u = a^x$; then (article 9), $\frac{du}{dx} = \text{l}.a\, a^x$,

$\frac{d^2u}{dx^2} = (\text{l}.a)^2\, a^x$, $\frac{d^3x}{dx^3} (\text{l}.a)^3\, a^x$, $\frac{d^4x}{dx^4} = (\text{l}.a)^4\, a^x$, &c.

(3.) Let $u = \log. x$; then (art. 20) $\frac{du}{dx} = \frac{\text{M}}{x}$,

$\frac{d^2u}{dx} = -\frac{\text{M}}{x^2}$, $\frac{d^3u}{dx^3} = -\frac{1\cdot2\text{M}}{x^3}$, $\frac{d^4u}{dx^4} = \frac{1\cdot2\cdot3\text{M}}{x^4}$, &c.

(4.) Let $u = \sin x$; then $\frac{du}{dx} = \cos x$,

$\frac{d^2u}{dx^2} = -\sin x$, $\frac{d^3u}{dx^3} = -\cos x$, $\frac{d^4u}{dx^4} = \sin x$, &c.

(5.) Let $u = \cos x$; then $\frac{du}{dx} = -\sin x$,

$\frac{d^2u}{dx^2} = -\cos x$, $\frac{d^3u}{dx^3} = \sin x$, $\frac{d^4u}{dx^4} = \cos x$, &c.

(6.) Let $u = \frac{a^2}{a^2 + x^2}$; then $\frac{du}{dx} = \frac{-2a^2x}{(a^2+x^2)^2}$,

$$\frac{d^2u}{dx^2} = \frac{-2a^4 + 6a^2x^2}{(a^2 + x^2)^3},$$

$$\frac{d^3u}{dx^3} = \frac{24a^4x - 24a^4x^3}{(a^2 + x^2)^4}, \text{ \&c.}$$

Taylor's Theorem.

28. We have assumed for the foundation of the differential calculus an important analytical principle, first particularly recognised by Euler, viz. Let $f(x)$ denote any function of a variable quantity x; if instead of x there be substituted $x + h$, h being any indeterminate quantity, so that the function becomes $f(x + h)$, this new value may always be expanded into a series of this form,

$$f(x) + ph + qh^2 + rh^3 +, \text{\&c.},$$

in which the quantities p, q, &c. are new functions of x derived from the primitive function, and independent of the indeterminate quantity h.

29. The truth of this principle has been exemplified by induction from particular cases. Lagrange has, however, given a demonstration of it in his *Théorie des Fonctions*, which is to the following effect:

In the first place, the development of the function $(x + h)$ cannot contain any fractional power of h, so long as x is entirely indeterminate. For the radicals of h can only come from radicals in the primitive function; and it is manifest that the substitution of $x + h$ instead of x can neither increase nor diminish their number, nor change their nature, while x and h are indeterminate. On the other hand, by the theory of equations, every radical expression has as many different values as there are units in its exponent; from which it follows, that every irrational function has as many distinct values as there are combinations of the different values of the radicals which it contains. Therefore, if the development of the function $f(x + h)$ could contain a term of the form $uh^{\frac{m}{n}}$, the function fx must necessarily be irrational, and contain a certain number of different values, which must be the same for its development; but this development being represented by the series $f(x) + ph + qh^2 +$, &c. $+ uh^{\frac{m}{n}} +$, &c. every value of the function $f(x)$ (the first term) might be combined with each of the n values of the radical $\sqrt[n]{x^m}$, so that the function $f(x + h)$ expanded would have more values than the same function unexpanded, which is impossible.

This demonstration is general and rigorous so long as x and h continue indeterminate; but it fails if determinate values be given to x, for it may happen that these values may destroy some radicals in the function $f(x)$, which may yet exist in the function $f(x + h)$.

30. It being proved that the development of the function cannot have any fractional powers of h, it is easy to be assured that it cannot contain negative powers. For if among the terms one had the form $\frac{r}{h^m}$, m being a positive integer number, then, in making $h = 0$, that term would become infinite, and the function $(x + h)$, and of course $f(x)$, would in this case be infinite, which cannot be, unless a particular value be given to x. Thus it is clearly established that the development of the function can contain neither fractional nor negative exponents.

31. The general form of the development of the function, viz.

$$f(x + h) = f(x) + ph + qh^2 + rh^3 +, \text{\&c.}$$

being thus ascertained, the next question is, what is the law of relation between the original function $f(x)$ and the functions p, q, r, &c. which are derived from it? We owe the discovery of this relation to a celebrated English mathematician, Brooke Taylor, who gave it in his *Methodus Incrementorum*, published in the year 1715 in the form of an analytical theorem, which is now called by his name: we shall now give its investigation. The following is that of Lagrange.

Let $f(x) = u$ be any function of x;
then, supposing x to become $x + h$, u becomes

$$f(x + h) = u + ph + qh^2 + rh^3 + sh^4 +, \text{\&c.}$$

Suppose now that x changes again its value, and becomes $x + k$, and here k, like h, is independent of x. Then

$$f(x + h) \text{ becomes } f(x + h + k).$$

There are two ways of finding what the series

$$f(x + h) = u + ph + qh^2 + rh^3 + sh^4 +, \text{\&c.}$$

becomes, when $x + h$ becomes $x + h + k$. 1st, We may have the value of the series by substituting $h + k$ in every term instead of h. 2dly, We may also have its value by substituting $x + k$ in the functions p, q, r, s, &c. for x; that is, instead of p, and q, and r, &c. we must put the values they have when $x + k$ is supposed to be substituted in them instead of x.

By the first-mentioned process we find $f(x + h + k) =$

$$\begin{array}{lllll} u + ph + qh^2 & + rh^3 & + sh^4 & +, \text{\&c.} \\ \quad + pk + 2qhk & + 3rh^2k & + 4sh^3k & +, \text{\&c.} \\ \qquad\qquad + qk^2 & + 3rhk^2 & + 6sh^2k^2 & +, \text{\&c.} \\ & + rk^3 & + 4shk^3 & +, \text{\&c.} \\ & & + sk^4, & +, \text{\&c.} \end{array}$$

And, in employing the second, it must be considered that, when x becomes $x + k$, then

$$u \text{ becomes } u + pk + qk^2 + rk^3 + sk^4 +, \text{\&c.}$$

because k here takes the place of h in the function $f(x + h)$, and its development $u + ph + qh^2 + rh^3 +$, &c.

The supposition that x changes its value to $x + k$, leads to corresponding changes in the functions p, q, r, &c.; so that

$$\begin{array}{ll} p \text{ becomes} & p + p'k + p''k^2 + p'''k^3 +, \text{\&c.} \\ q \;\; . \;\; . \;\; . & q + q'k + q''k^2 + q'''k^3 +, \text{\&c.} \\ r \;\; . \;\; . \;\; . & r + r'k + r''k^2 + r'''k^3 +, \text{\&c.} \\ s \;\; . \;\; . \;\; . & s + s'k + s''k^2 + s'''k^3 +, \text{\&c.} \\ \quad \text{\&c.} & \end{array}$$

Direct Method.

Here p', p'', &c. denote functions of x derived from p, just as p, q, r, &c. are derived from the function u; and a like remark applies to q', q'', &c. also to r', r'', &c. and so on. Substituting now these new values of u, p, q, r, &c. in the series $u + ph + qh^2 + rh^3 + sh^4 +$, &c. we have $f(x + h + k) =$

$$\begin{array}{llllll} u + pk & + qk^2 & + rk^3 & + sk^4 & +, \&c. \\ + ph & + p'hk & + p''hk^2 & + p'''hk^3 & +, \&c. \\ & + qh^2 & + q'h^2k & + q''h^2k^2 & +, \&c. \\ & & + rh^3 & + r'h^3k & +, \&c. \\ & & & + sh^4 & +, \&c. \end{array}$$

By comparing the co-efficients of like powers, or products of powers, of h and k in the two expressions for $f(x + h + k)$, it appears that, to make them identical, we must have

$$2q = p',\ 3r = q',\ 4s = r', \text{ and so on.}$$

$$\text{Therefore } q = \frac{p'}{2}, r = \frac{q'}{3}, s = \frac{r'}{4}, \&c.$$

Now, by the definition of a differential, pdx is the differential of u, where p is the co-efficient of h in the series $u + ph + qh^2 +$, &c. Therefore $p = \frac{du}{dx}$. Similarly, $q'dx$ is the differential of q, where q' is the co-efficient of k in the development $q — q'k + q''k^2 +$, &c. Therefore, $q' = \frac{dq}{dx}$; and in like manner, $r' = \frac{dr}{dx}$ and $s' = \frac{ds}{dx}$, and so on; hence

$$p = \frac{dy}{dx},$$

$$q = \tfrac{1}{2}p' = \tfrac{1}{2}\frac{dp}{dx} = \frac{1}{1.2}\,\frac{d^2u}{dx^2},$$

$$r = \tfrac{1}{3}q' = \tfrac{1}{3}\frac{dq}{dx} = \frac{1}{1.2.3}\,\frac{d^3u}{dx^3},$$

$$s = \tfrac{1}{4}r' = \tfrac{1}{4}\frac{dr}{dx} = \frac{1}{1.2.3.4}\,\frac{d^4u}{dx^4},$$

&c.

These values of p, q, r, s, &c. being substituted in the series $u + ph + qh^2 + rh^3 + sh^4 +$, &c. we obtain $f(x + h) =$

$$u + \frac{du}{dx}h + \frac{d^2u}{dx^2}\,\frac{h^2}{1.2} + \frac{d^3u}{dx^3}\,\frac{h^3}{1.2.3} + \frac{d^4u}{dx^4}\,\frac{h^4}{1.2.3.4} +, \&c.$$

where $u = f(x)$; this is Taylor's theorem.

32. We shall now give another investigation of this important formula, which is remarkable for its brevity and simplicity. It rests on the following analytic principle.

If u *be any function whatever of* v + z, *which relation may be expressed thus,* u = f (v+z); *the differential co-efficient of* u, *found on the supposition that* v *is variable and* z *constant, will be the very same as if it were found on the supposition that* z *is variable and* v *constant.*

To exemplify this in particular cases, suppose $u = (v+z)^n$, then, making v variable and z constant, $\frac{du}{dv} = n(v+z)^{n-1}$; and making z variable and v constant, $\frac{du}{dz} = n(v+z)^{n-1}$, the same as before. Again, let $u = a^{v+z} = a^v\ a^z$, then $\frac{du}{dv}$ and $\frac{du}{dz}$ are expressed by the same quantity $\text{l}.a.a^v\ a^z = \text{l}.a.a^{v+z}$.

The truth of the principle is almost self-evident; for if we make $v + z = x$, so that $f(v + z) = f(x)$; then, whether we suppose v to vary and to become $v + h$, while z remains the same, or z to vary and become $z + h$, while v remains constant, the result is the very same, viz.

$$f(v + z + h) = f(x + h);$$

therefore, in the development of $f\,(v + z + h) = f(x + h)$, viz.

$$f(x) + ph + qh^2 + rh^3 +, \&c.$$

in which p, q, &c. are functions of x; that is, of $v + z$, these functions will be the very same, whichever of the two, v and z, has been considered as the variable, the other remaining constant. Now, by the nature of a differential (art. 7), we have

$$p = \frac{d\{f(x)\}}{dx} = \frac{d\{f(v+z)\}}{d(v+z)};$$

and upon the supposition that v is variable and z constant, then

$$p = \frac{d\{f(v+z)\}}{dv};$$

but supposing z variable and v constant,

$$p = \frac{d\{f(v+z)\}}{dz};$$

$$\text{therefore } \frac{d\{f(v+z)\}}{dv} = \frac{d\{f(v+z)\}}{dz};$$

the first side of this equation being the result of the differentiation, supposing v variable, and the second the result, on the hypothesis that z is variable. Since the two expressions $\frac{d\{f(v+z)\}}{dv}$ and $\frac{d\{(v+z)\}}{dz}$ are identical and the same function of $v + z$, we may represent that function by the symbol $\mathrm{F}(v + z)$; then, by reasoning as before, we shall have

$$\frac{d\{\mathrm{F}(v+z)\}}{dv} = \frac{d\{\mathrm{F}(v+z)\}}{dz},$$

$$\text{that is, } \frac{d^2\{f(v+z)\}}{dv^2} = \frac{d^2\{f(v+z)\}}{dz^2}.$$

Thus it appears that the second differential co-efficient of the function $f\,(v + z)$ is the same expression, whether v or z be regarded as the variable; and the reasoning may be extended to the co-efficient of any order.

33. Supposing now $f(x) = u$ to be any function of x, and $f(x + h) = u'$ to be its value when x becomes $x + h$, it has been proved (art. 29, 30), that the expansion of u is

$$u' = u + ph + qh^2 + rh^3 + sh^4;$$

and here p, q, r, &c. are functions of x, into which x does not at all enter; while, on the other hand, h is entirely independent of x. From the identity of the function u' and its expansion, their differentials, taken on the same hypothesis, must be equal, whichever of the quantities x and h be regarded as the variable. Supposing, first, x variable and h constant, we have

$$\frac{du'}{dx} = \frac{du}{dx} + \frac{dp}{dx}h + \frac{dq}{dx}h^2 + \frac{dr}{dx}h^3 + \frac{ds}{dx}h^4 +, \&c.$$

and next, supposing h to be variable and x constant,

$$\frac{du}{dh} = ph + 2qh + 3rh^2 + 4sh^3 +, \&c.$$

Now it has been shown in last article that $\frac{du'}{dx} = \frac{du'}{dh}$; therefore the series which are their expansions must be identical; and hence the terms independent of h must be equal, also the co-efficients of the same power of h, so that

$$p = \frac{du}{dx},\quad 2q = \frac{dp}{dx},\quad 3r = \frac{dq}{dx},\quad 4s = \frac{dr}{dx}, \&c.;$$

Direct Method.

and since $p = \frac{du}{dx}$, therefore $q = \frac{1}{2}\frac{dp}{dx} = \frac{1}{2}\frac{d^2u}{dx^2}$, and $r = \frac{1}{3}\frac{dq}{dx} = \frac{1}{2.3}\frac{d^3u}{dx^3}$; also $s = \frac{1}{4}\frac{dr}{dx} = \frac{1}{2.3.4}\frac{d^4u}{dx^4}$, &c.; and, on the whole, $f(x+h) =$

$$u' = u + \frac{du}{dx}h + \frac{d^2u}{dx^2}\frac{h^2}{2} + \frac{d^3u}{dx^3}\frac{h^3}{2.3} + \frac{d^4u}{dx^4}\frac{h^4}{2.3.4} +, \&c.$$

From this formula it appears, that if h be the increment of the variable x; the whole increment of u, any function of x, is

$$u' - u = \frac{du}{dx}\frac{h}{1} + \frac{d^2u}{dx^2}\frac{h^2}{1.2} + \frac{d^3u}{dx^3}\frac{h^3}{1.2.3} +, \&c.$$

a series composed of the successive differential co-efficients of the function, each multiplied by an integer power of h, and divided by the products 1, 1 . 2, 1 . 2 . 3, &c.

Application of Taylor's Theorem to the Development of Functions.

We shall now give some applications of this most important analytic formula to the development of functions.

34. Let the function $f(x)$ be $u = x^n$, so that $f(x+h) = (x+h)^n$. By successive differentiation (art. 13 and 27), $\frac{du}{dx} = nx^{n-1}$, $\frac{d^2u}{dx^2} = n(n-1)x^{n-2}$, $\frac{d^3u}{dx^3} = n(n-1)(n-2)x^{n-3}$, $\frac{d^4u}{dx^4} = n(n-1)(n-2)(n-3)x^{n-4}$, &c.

These differential co-efficients, when substituted in the formula, give

$$(x+h)^n = x^n + nx^{n-1}h + \frac{n(n-1)}{1.2}x^{n-2}h^2 + \frac{n(n-1)(n-2)}{1.2.3}x^{n-3}h^3 +, \&c.$$

This is the well-known binomial theorem (ALGEBRA, art. 160).

35. Next, let $f(x)$ be $u = a^x$, a variable power of the constant quantity a. Then, putting

$$\mathrm{A} = (a-1) - \tfrac{1}{2}(a-1)^2 + \tfrac{1}{3}(a-1)^3 - \tfrac{1}{4}(a-1)^4 +, \&c.$$

By article 19, $\frac{du}{dx} = \mathrm{A}a^x$, $\frac{d^2u}{dx^2} = \mathrm{A}^2 a^x$, $\frac{d^3u}{dx^3} = \mathrm{A}^3 a^x$,

$$\frac{d^4u}{dx^4} = \mathrm{A}^4 a^x, \&c.$$

Remarking now that $f(x+h) = a^{x+h} = a^x\, a^h$, we have

$$a^x a^h = a^x\left\{1 + \mathrm{A}h + \frac{\mathrm{A}^2h^2}{1.2} + \frac{\mathrm{A}^3h^3}{1.2.3} + \frac{\mathrm{A}^4h^4}{1.2.3.4} +, \&c.\right\};$$

and dividing both sides by a^x, and changing h into x,

$$a^x = 1 + \mathrm{A}x + \frac{\mathrm{A}^2x^2}{1.2} + \frac{\mathrm{A}^3x^3}{1.2.3} + \frac{\mathrm{A}^4x^4}{1.2.3.4} +, \&c.$$

If we suppose $x = 1$, then,

$$a = 1 + \mathrm{A} + \frac{\mathrm{A}^2}{1.2} + \frac{\mathrm{A}^3}{1.2.3} + \frac{\mathrm{A}^4}{1.2.3.4} +, \&c.$$

and if we make $x = \frac{1}{\mathrm{A}}$, we have

$$a^{\frac{1}{\mathrm{A}}} = 1 + 1 + \frac{1}{1.2} + \frac{1}{1.2.3} + \frac{1}{1.2.3.4} +, \&c.$$

Hence it appears that $a^{\frac{1}{\mathrm{A}}}$ is a constant number, which is the sum of this series. By taking the sum of a sufficient number of its terms, we find

$$a^{\frac{1}{\mathrm{A}}} = 2{\cdot}718281828459.$$

Let this number, which will frequently recur, be denoted by the letter e, and we have

$a^{\frac{1}{\mathrm{A}}} = c$, and $a = e^{\mathrm{A}}$ and

$$e^{\mathrm{A}x} = a^x = 1 + \mathrm{A}x + \frac{\mathrm{A}^2x^2}{1.2} + \frac{\mathrm{A}^3x^3}{1.2.3} + \frac{\mathrm{A}^4x^4}{1.2.3.4} +, \&c.;$$

and making $y = \mathrm{A}x$, so that y may be any number,

$$e^y = 1 + y + \frac{y^2}{1.2} + \frac{y^3}{1.2.3} + \frac{y^4}{1.2.3.4} +, \&c.$$

This formula expresses a remarkable property of the number e.

36. Let the function $f(x)$ be $u = \log x$ to base a, then, by article 20,

$$\frac{du}{dx} = \frac{1}{\mathrm{A}x},\ \frac{d^2u}{dx^2} = \frac{-1}{\mathrm{A}x^2},\ \frac{d^3u}{dx^3} = \frac{1.2}{\mathrm{A}x^3}, \&c.$$

$$\frac{d^4u}{dx^4} = -\frac{1.2.3}{\mathrm{A}x^4},\ \frac{d^5u}{dx^5} = \frac{1.2.3.4.5}{\mathrm{A}x^5}; \&c.$$

Hence, by the theorem, $f(x+h) = \log(x+h) = \log x + \frac{1}{\mathrm{A}}\left\{\frac{h}{x} - \frac{h^2}{2x^2} + \frac{h^3}{3x^3} - \frac{h^4}{4x^4} + \frac{h^5}{5x^5} -, \&c.\right\}$.

Make $x = 1$, and observe that $\log 1 = 0$, and change h into x, and we have

$$\log(1+x) = \frac{1}{\mathrm{A}}\left\{x - \tfrac{1}{2}x^2 + \tfrac{1}{3}x^3 - \tfrac{1}{4}x^4 +, \&c.\right\}$$

This is the logarithm of $1+x$ in the system whose base is a.

In the preceding article we found that $a = e^{\mathrm{A}}$, hence, from the theory of logarithms (ALGEBRA, sect. xix.), A is the logarithm of a to the base e. Now

$$\mathrm{A} = a - 1 - \tfrac{1}{2}(a-1)^2 + \tfrac{1}{3}(a-1)^3 - \tfrac{1}{4}(a-1)^4, +, \&c.$$

Therefore, in the system whose base is e,

$$\log a = a - 1 - \tfrac{1}{2}(a-1)^2 + \tfrac{1}{3}(a-1)^3 - \tfrac{1}{4}(a-1)^4;$$

and hence, putting $1+x$ for a, and x for $a-1$, in that system,

$$\log(1+x) = x - \tfrac{1}{2}x^2 + \tfrac{1}{3}x^3 - \tfrac{1}{4}x^4 +, \&c.$$

Now we found that in the system whose base is a,

$$\log(1+x) = \frac{1}{\mathrm{A}}\{x - \tfrac{1}{2}x^2 + \tfrac{1}{3}x^3 - \tfrac{1}{4}x^4 +, \&c.\}$$

By comparing these two expressions for $\log(1+x)$, it appears that in the system whose base is e, the constant quantity A, which is

$$e - 1 - \tfrac{1}{2}(e-1)^2 + \tfrac{1}{3}(e-1)^3 - \tfrac{1}{4}(e-1)^4 +, \&c.$$

is equal to unity. Logarithms computed according to this system are the same as those first given to the world by Napier, the celebrated inventor of logarithms, who was, however, led to them by a very different path from that here followed. It so happens that the same logarithms express hyperbolic areas, and hence they were called *hyperbolic* logarithms, a distinction quite improper, because hyperbolic areas may be expressed by logarithms of any system. Accordingly, it is now common to denominate them, in honour of the inventor, *Napierian* logarithms. In speaking of these, then, it must be understood that their base is $e = 2{\cdot}718281828459$, &c.; and remembering that the letter l prefixed to any expression of a function means *Napier's logarithm* of that function (art. 19).

$$\mathrm{l.}\,(1+x) = x - \tfrac{1}{2}x^2 + \tfrac{1}{3}x^3 -, \tfrac{1}{4}x^4 +, \&c.$$

and since A = Nap. log a (see last article), therefore in the system whose base is a,

$$\log(1+x) = \frac{1}{\mathrm{l.}\,a}\{x - \tfrac{1}{2}x^2 + \tfrac{1}{3}x^3 - \tfrac{1}{4}x^4 +, \&c.\}$$

Direct Method.

The constant multiplier $\frac{1}{\text{l. }a}$, called the *modulus* of the system, is, for Briggs's logarithms,

$$\frac{1}{\text{l. }(10)} = \cdot 4342944819033 \text{ —, and its reciprocal,}$$

$$\text{l. }(10) = 2\cdot 302585092994.$$

37. Let the function be $fx = u = \sin x$, then

$$\frac{du}{dx} = +\cos x, \frac{d^2u}{dx^2} = -\sin x, \frac{d^3u}{dx^3} = -\cos x,$$

$$\frac{d^4u}{dx^4} = +\sin x, \frac{d^5u}{dx^5} = +\cos x, \text{ \&c.}$$

These values of the differential co-efficients being substituted in the theorem, it gives $f(x+h) = \sin(x+h)$

$$= \sin x + \cos x \frac{h}{1} - \sin x \frac{h^2}{1.2} - \cos x \frac{h^3}{1.2.3} + \sin x \frac{h^4}{1.2.3.4} +, \text{ \&c.}$$

$$= \begin{cases} \sin x \left(1 - \frac{h^2}{2} + \frac{h^4}{2.3.4} - \frac{h^6}{2.3.4.5.6} +, \text{ \&c.}\right) \\ + \cos x \left(h - \frac{h^3}{2.3} + \frac{h^5}{2.3.4.5} - \frac{h^7}{2.3.4.5.6.7} +, \text{ \&c.}\right) \end{cases}$$

Let the function be $fx = u = \cos x$, then

$$\frac{du}{dx} = -\sin x, \frac{d^2u}{dx^2} = -\cos x, \frac{d^3u}{dx^3} = \sin x,$$

$$\frac{d^4u}{du^4} = \cos x, \frac{d^5u}{dx^5} = -\sin x, \text{ \&c.}$$

and by substituting in the formula $f(x+h) = \cos(x+h)$

$$= \cos x - \sin x \frac{h}{1} - \cos x \frac{h^2}{2} + \sin x \frac{h^3}{2.3} + \cos x \frac{h^4}{2.3.4} -, \text{ \&c.}$$

$$= \begin{cases} \cos x \left(1 - \frac{h^2}{2} + \frac{h^4}{2.3.4} - \frac{h^6}{2.3.4.5.6} +, \text{ \&c.}\right) \\ - \sin x \left(h - \frac{h^3}{2.3} + \frac{h^5}{2.3.4.5} - \frac{h^7}{2.3.4.5.6.7} +, \text{ \&c.}\right) \end{cases}$$

$$\text{Put } P = 1 - \frac{h^2}{2} + \frac{h^4}{2.3.4} - \frac{h^6}{2.3.4.5.6} +, \text{ \&c.}$$

$$Q = h - \frac{h^3}{2\cdot 3} + \frac{h^5}{2.3.4.5} - \frac{h^7}{2.3.4.5.6.7} +, \text{ \&c.}$$

Then $\sin(x+h) = P \sin x + Q \cos x$,
$\cos(x+h) = P \cos x - Q \sin x$.

Hence, by eliminating Q and P in succession,
$\sin(x+h) \sin x + \cos(x+h) \cos x = P$,
$\sin(x+h) \cos x - \cos(x+h) \sin x = Q$.

Therefore (Algebra, 239), $\cos h = P$, $\sin h = Q$; and exchanging h for x,

$$\cos x = 1 - \frac{x^2}{2} + \frac{x^4}{2.3.4} - \frac{x^6}{2.3.4.5.6} +, \text{ \&c.}$$

$$\sin x = x - \frac{x^3}{2.3} + \frac{x^5}{2.3.4.5} - \frac{x^7}{2.3.4.5.6.7} +, \text{ \&c.}$$

The same results might have been obtained easier by making $x = 0$ in the series for $\sin(x+h)$ and $\cos.(x+h)$.

38. Let the function be the arc whose tangent is x, that is, $u = \tan^{-1} x$;

$$\text{then } du = \frac{dx}{1+x^2} = dx \cos^2 u \text{ (art. 23),}$$

$$\text{and } \frac{du}{dx} = \cos u \cos u.$$

The succeeding differential co-efficients will be found by formulæ (1) and (2) of article 26.

$$\text{By (1) } \frac{d^2u}{dx^2} = -\sin 2u \cos^2 u,$$

$$\text{By (2) } \frac{d^3u}{dx^3} = -2 \cos 3u \cos^3 u,$$

$$\text{By (1) } \frac{d^4u}{dx^4} = 2.3 \sin 4u \cos^4 u,$$

$$\text{By (2) } \frac{d^5u}{dx^5} = 2.3.4 \cos 5u \cos^5 u,$$

$$\text{By (1) } \frac{d^6u}{dx^6} = 2.3.4.5 \sin 6u \cos^6 u,$$

$$\text{By (2) } \frac{d^7u}{dx^7} = -2.3.4.5.6 \cos 7u \cos^7 u, \text{ \&c.}$$

Hence, if we put $\tan u = x$, and $\tan u' = x+h$, we deduce from Taylor's theorem this very general and remarkable formula:

$$u' = u + \cos u \cos u . \frac{h}{1} - \sin 2u \cos^2 u \frac{h^2}{2} - \cos 3u \cos^3 u \frac{h^3}{3}$$

$$+ \sin 4u \cos^4 \frac{h^4}{4} + \cos 5u \cos^5 u \frac{h^5}{5}$$

$$- \sin 6u \cos^6 u \frac{h^6}{6} -, \text{ \&c.}$$

If the arc u be supposed $= 0$, then $\sin u$, $\sin 2u$, &c. are each 0, and the powers of $\cos u$ each $= 1$, and the formula becomes

$$u = \tan u - \frac{1}{3} \tan^3 u + \frac{1}{5} \tan^5 u - \frac{1}{7} \tan^7 u +, \text{ \&c.}$$

a formula due to James Gregory. We have found this series in a very different way (Algebra, art. 270), and have there applied it to the determination of the ratio of the diameter to the circumference. It will be therefore sufficient to state the result here. Let π denote half the circumference of a circle, of which the rad. $= 1$, then

$$\pi = 3\cdot 141592653590 \text{ —.}$$

Maclaurin's Theorem.

39. There is a general formula nearly related to that of Taylor, and indeed an easy deduction from it, commonly called *Maclaurin's Theorem.* It is given at page 610 of the second volume of his fluxions (printed in 1742); but it is proper to say, that the same formula, in substance, was given in 1717 by Stirling, in his *Lineæ Tertii Ordines Neutonianæ*, p. 32.

We have found that $f(x) = u$ being any function of a variable x,

$$f(x+h) = u + \frac{du}{dx} h + \frac{d^2u}{dx^2} \frac{h^2}{2} + \frac{d^3u}{dx^3} \frac{h^3}{2.3} + \frac{d^4u}{dx^4} \frac{h^4}{2.3.4} +, \text{ \&c.}$$

Suppose now that $x = 0$, and that by making this assumption

$f(x) = u$ becomes U,
also that $\frac{du}{dx}$ becomes U',
$\frac{d^2u}{dx^2}$ .... U'',
$\frac{d^3u}{dx^3}$ .... U''',
&c.

Then Taylor's theorem becomes

$$f(h) = U + U'h + U'' \frac{h^2}{1.2} + U''' \frac{h^3}{1.2.3} +, \text{ \&c.}$$

or, changing h into x,

$$f(x) = U + U'x + U'' \frac{x^2}{1.2} + U''' \frac{x^3}{1.2.3} +, \text{ \&c.}$$

From this it appears, that provided u be such a function of x as admits of being expanded into a series of the form

$$u = A + Bx + Cx^2 + Dx^3 +, \text{ \&c.}$$

where A, B, C, D, &c. are constant quantities, then, U being the value of u when $x = 0$, and U', U'', U''', &c. being the values of the differential co-efficients $\frac{du}{dx}, \frac{d^2u}{dx^2}, \frac{d^3u}{dx^3}$, &c. found on that hypothesis, we have

$$A = U, B = U', C = U'', D = U''', \text{\&c.}$$

and consequently,

$$u = U + U'x + U''\frac{x^2}{2} + U'''\frac{x^3}{2 . 3} +, \text{\&c.}$$

This is Maclaurin's theorem, of which we shall now give some applications.

40. Let $u = (a + x)^n$. The expansion of this expression has the requisite form; then $\frac{du}{dx} = n(a + x)^{n-1}$,

$$\frac{d^2u}{dx^2} = n(n-1)(a + x)^{n-2},$$

$$\frac{d^3u}{dx^3} = n(n-1)(n-2)(a + x)^{n-3}, \text{\&c.}$$

The supposition that $x = 0$ makes

$$u = a^n = U, \frac{du}{dx} = na^{n-1} = U', \frac{d^2x}{dx^2} = n(n-1)a^{n-2} = U'',$$

$$\frac{d^3u}{dx^3} = n(n-1)(n-2)a^{n-3} = U''', \text{\&c.}$$

The proper substitutions being made in the general theorem, we have

$$(a + x)^n = a^n + na^{n-1}x + \frac{n(n-1)}{1 . 2}a^{n-2}x^2$$
$$+ \frac{n(n-1)(n-2)}{1 . 2 . 3}a^{n-3}x^3 +, \text{\&c.}$$

41. Let $u = a^x$. This function is also of the kind that admits of expansion by the theorem; the differential coefficients are (art. 19), putting $A = l. a$,

$$\frac{du}{dx} = Aa^x, \quad \frac{d^2u}{dx^2} = A^2a^x, \quad \frac{d^3u}{dx^3} = A^3a^x, \text{\&c.}$$

The supposition that $x = 0$ gives $u = 1$, and

$$\frac{du}{dx} = A, \quad \frac{d^2u}{dx^2} = A^2, \quad \frac{d^3u}{dx^3} = A^3, \text{\&c.}$$

$$\text{Hence } a^x = 1 + Ax + \frac{A^2x^2}{1 . 2} + \frac{A^3x^3}{1 . 2 . 3} +, \text{\&c.}$$

as was found in art. 35.

42. The formula $u = \log x$ does not admit of being expanded into a series of the prescribed form, for in this case $\frac{du}{dx} = \frac{1}{Ax}$; the supposition that $x = 0$ makes u and $\frac{du}{dx}$, as well as all the following differential co-efficients, infinite. The function $u = \log(n + x)$, however, admits of the application of the formula. In this case (art. 20),

$$\frac{du}{dx} = \frac{1}{A(n + x)}, \frac{d^2u}{dx^2} = \frac{-1}{A(n+x)^2}, \frac{d^3u}{dx^3} = \frac{1 . 2}{A(n+x)^3}, \text{\&c.}$$

The assumption that $x = 0$ makes $u = \log n = U$, and

$$\frac{du}{dx} = \frac{1}{An} = U', \frac{d^2u}{dx^2} = -\frac{1}{An^2} = U'', \frac{d^3u}{dx^3} = \frac{1 . 2}{An^3} = U''', \text{\&c.}$$

We have now, by the general formula,

$$\log(n + x) = \log n + \frac{1}{A}\left\{\frac{x}{n} - \frac{x^2}{2n} + \frac{x^3}{3n} -, \text{\&c.}\right\}.$$

By making $n = 1$, and therefore $\log n = 0$, we have the expression for $\log(1 + x)$, as already found.

43. The theorem may be applied to the functions $u = \sin x$, and $u = \cos x$, without the least difficulty. For the first we have

$$U = 0, \quad U' = 1, \quad U'' = 0, \quad U''' = -1, \text{\&c.}$$

$$\text{and } \sin x = x - \frac{x^3}{1 . 2 . 3} + \frac{x^5}{1 . 2 . 3 . 4 . 5} +, \text{\&c.};$$

for the second function

$$U = 1, \quad U' = 0, \quad U'' = -1, \quad U''' = 0, \text{\&c.}$$

$$\cos x = 1 - \frac{x^2}{1 . 2} + \frac{x^4}{1 . 2 . 3 . 4} - \frac{x^6}{1 . 2 . 3 . 4 . 5 . 6} +, \text{\&c.}$$

44. Let u denote the arc whose sine is x; that is, let $u = \sin^{-1} x$. In this case (23),

$$\frac{du}{dx} = (1 - x^2)^{-\frac{1}{2}},$$

$$\frac{d^2u}{dx^2} = x(1 - x^2)^{-\frac{3}{2}},$$

$$\frac{d^3u}{dx^3} = (1 - x^2)^{-\frac{3}{2}} + 3x^2(1 - x)^{-\frac{5}{2}},$$

$$\frac{d^4u}{dx^4} = 3 . 3x(1 - x^2)^{-\frac{5}{2}} + 3 . 5x^3(1 - x^2)^{-\frac{7}{2}},$$

&c.

Making $x = 0$ we get $U = 0$, $U' = 1$, $U'' = 0$, $U''' = 1$, $U^{\text{IV}} = 0$; and, by continuing the process of differentiation, $U^{\text{V}} = 3 . 3$, &c. therefore

$$u = x + \frac{x^3}{1 . 2 . 3} + \frac{3 . 3x^5}{1 . 2 . 3 . 4 . 5} + \frac{3^2 . 5^2x^7}{1 . 2 . 3 . 4 . 5 . 6 . 7} +, \text{\&c.}$$

Cases in which Taylor's Theorem fails.

45. We have seen that Taylor's theorem, viz. $u = f(x)$ being any function of a variable x,

$$f(x + h) = u + \frac{du}{dx}\frac{h}{1} + \frac{d^2u}{dx^2}\frac{h^2}{1 . 2} + \frac{d^3u}{dx^3}\frac{h^3}{1 . 2 . 3} +, \text{\&c.}$$

will always hold true, provided that the variable x be regarded as indeterminate. If however particular values be given to x, there are cases in which the development is of no use, because in these cases it is not applicable to the function.

For example, let $u = b + (x - a)^{\frac{1}{2}}$; in this case,

$$\frac{du}{dx} = \frac{1}{2(x - a)^{\frac{1}{2}}}, \frac{d^2u}{dx^2} = -\frac{1}{4(x - a)^{\frac{3}{2}}}, \text{\&c.}$$

and by the theorem,

$$f(x + h) = b + (x - a + h)^{\frac{1}{2}} = b + (x - a)^{\frac{1}{2}}$$
$$+ \frac{1}{2(x - a)^{\frac{1}{2}}}h - \frac{1}{8(x - a)^{\frac{3}{2}}}h^2 +, \text{\&c.}$$

Now if we give to x any particular value greater than a, the development is perfectly significant, and expresses truly the value of $b + (x - a + h)^{\frac{1}{2}}$. If however we give to x the particular value a, then $x - a = 0$, and the development becomes $b + 0 + \frac{h}{2(0)^{\frac{1}{2}}} - \frac{h^2}{8(0)^{\frac{3}{2}}} +$, &c. from which no conclusion whatever can be drawn, because all the terms having *zero* in the denominator are infinite.

If in the expression $b + (x - a + h)^{\frac{1}{2}}$ we make $x = a$, it becomes $b + h^{\frac{1}{2}}$. This expression has two values, viz. $b + \sqrt{h}$, $b - \sqrt{h}$. The development given by the theorem contains, however, only positive integer powers of h; therefore it can have only a single value; and hence it is impossible that it should express the function in the particular case of $x = a$. In such cases the theorem has been said to *fail*; this however happens not from any imperfection in the theorem, but merely because it is unsuitable to the purpose to which it has been applied; and this want of applicability is indicated by the co-efficients of the powers of h failing to express any thing definite.

46. Again, let the function be $u = \frac{b}{(x - a)^2}$; then

$$\frac{du}{dx} = -\frac{2b}{(x-a)^3}, \frac{d^2u}{dx^2} = \frac{6b}{(x-a)^4}, \text{ \&c.}$$

In this case

$$f(x+h) = \frac{b}{(x-a+h)^2} = \frac{b}{(x-a)^2} - \frac{2b}{(x-a)^3}h$$
$$+ \frac{3b}{(x-a)^4}h^2 -, \text{ \&c.}$$

Here x may have any particular value greater or less than a, and the development will be perfectly significant; if, however, x be equal to a, it becomes

$$\frac{b}{(o)^2} - \frac{2b}{(o)^3}h + \frac{3b}{(o)^4}h^2 -, \text{ \&c.};$$

an expression that has no meaning, because each of the co-efficients of h is infinite.

If we make $x = a$ in $\frac{b}{(x+a+h)^2}$, the function to be expanded, it becomes $\frac{b}{b^2} = bh^{-2}$, an expression in which the exponent of h is negative; therefore this case cannot be included in a formula which contains only positive integers of h, and hence the apparent failure of the theorem.

47. That a general formula should not express all particular cases, was at one time regarded as a kind of paradox in analysis. Lagrange first cleared up this point, and showed, that when by giving particular values to x, the new state of the function contains terms of the form Ph^{-n}, or $Qh^{\frac{m}{n}}$, that is, negative or fractional powers of h, then, from the very nature of the calculus, all the co-efficients in the general development after a certain term will become infinite. On the other hand, when a particular value of x renders the co-efficients infinite, we may conclude that the development in that case ought to contain fractional or negative powers of h. In such particular cases as appear not to admit of expansion by Taylor's theorem, other methods deducible from the calculus are applicable; in general, the ordinary algebraic methods are sufficient.

Differentiation of Equations of two Variables.

48. We have as yet differentiated only equations in which the variables were separated, such as this, $y = a + bx + cx^2$, where y is an implicit function of x. But the equations which chiefly occur in analytical inquiries contain for the most part the two variables combined or mixed together; as in this equation,

$$y^2 - 2mxy + x^2 - a^2 = 0.$$

If we suppose the equation resolved, so that y is expressed in terms of x only, which gives

$$y = mx \pm \sqrt{a^2 + (m^2-1)x^2},$$

the differentials may be found by the rules already explained. In general, however, the variables cannot be so separated, and therefore it is necessary that we be able to determine the differential co-efficients of a function by other means.

49. An equation formed in any way from two independent variable quantities may be represented by the general symbol

$$f(x, y) = 0.$$

The variable y must be expressible in some way by x; therefore we may represent its value, however found, by the equation $y = X$, where X denotes an expression made up of terms containing only x and constant quantities. When this value of y is substituted in the equation, it becomes

$$f(x, X) = 0.$$

This is an identical equation, involving x only, which must hold true whatever value be given to x. Let the expression $f(x, X) = f(x, y)$ be denoted briefly by u. Suppose now x to change its value and become $x + h$; by Taylor's theorem, its new values will be

$$u' = u + \frac{du}{dx}h + \frac{d^2u}{dx^2}h^2 + \frac{d^3u}{dx^3}h^3 +, \text{ \&c.}$$

The equation $f(x, y) = u = 0$ must hold true whatever value be given to x; therefore we must have $u' = 0$, and this requires that the co-efficients of the different powers of the indeterminate quantity h be separately $= 0$ (art. 18), so that from the equation $u = f(x, y) = 0$ there may be derived a series of equations,

$$\frac{du}{dx} = 0, \frac{d^2u}{dx^2} = 0, \frac{d^3u}{dx^3} = 0, \text{ \&c.}$$

which must all hold true at the same time as the original equation.

50. Let us take for example the equation

$$y^2 + x^2 = a^2, \text{ or } y^2 + x^2 - a^2 = 0 \ldots\ldots\ldots (1.)$$

in which a is a constant quantity; in this case,

$$u = y^2 + x^2 - a^2;$$

hence we have by differentiation

$$\frac{du}{dx} = 2y\frac{dy}{dx} + 2x = 0,$$

$$\text{and } \frac{dy}{dx} = -\frac{x}{y} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (2.).$$

To determine the differential co-efficient of the second order, put $\frac{dy}{dx} = p$, and we have

$$\frac{du}{dx} = 2yp + 2x;$$

as p is a function of x and y, and y is a function of x, therefore p is a function of x. Taking now the differentials, and dividing by dx, the result is

$$\frac{d^2u}{dx^2} = 2\left(y\frac{dp}{dx} + p\frac{dy}{dx} + 1\right) = 0;$$

hence, because $p = \frac{dy}{dx}$, and $\frac{dp}{dx} = \frac{d^2y}{dx^2}$,

$$\frac{d^2u}{dx^2} = 2\left(y\frac{d^2y}{dx^2} + \frac{dy^2}{dx^2} + 1\right) = 0 \ldots\ldots\ldots\ldots\ldots (3.)$$

From this equation we get

$$\frac{d^2y}{dx^2} = -\frac{1}{y}\left(\frac{dy^2}{dx^2} + 1\right),$$

$$\text{or, since } \frac{dy}{dx} = -\frac{x}{y},$$

$$\frac{d^2y}{dx^2} = -\frac{x^2}{y^3} - \frac{1}{y} \ldots\ldots\ldots\ldots\ldots\ldots (4.)$$

To find the differential co-efficient of the third order, we put $\frac{d^2y}{dx^2} = \frac{dp}{dx} = q$; and substituting p for $\frac{dy}{dx}$ in equation (3), it becomes

$$\frac{d^2u}{dx^2} = 2(yq + p^2 + 1) = 0;$$

observing that p and q are functions of x and y, and consequently of x, we may find by differentiation an expression which will involve, besides x and y, these quantities,

$$\frac{dq}{dx}, \frac{dp}{dx} = \frac{d^2y}{dx^2}, q = \frac{d^2y}{dx^2}, p = \frac{py}{dx};$$

and from this equation $\frac{dq}{dx} = \frac{d^3y}{dx^3}$ may be determined, observing that $\frac{d^2y}{dx^2}$ and $\frac{dy}{dx}$ are expressed by x and y in equations (4) and (2).

51. The preceding analysis gives the following rule for

Direct Method.

determining the differential co-efficients of y, a function of x, when the relation between x and y is expressed by an equation.

Take the differentials of the terms of the equation, considering y as a function of x, and dividing by dx, the result will be an equation which gives the value of $\frac{dy}{dx}$. Again, take the differentials of the terms of this equation, considering y and $\frac{dy}{dx}$ as functions of x, and the result will be an equation involving $\frac{d^2y}{dx^2}$ and $\frac{dy}{dx}$, which, combined with the former, serves to determine $\frac{d^2y}{dx^2}$. A third equation may be found from this, by taking the differentials, and considering y, $\frac{dy}{dx}$, and $\frac{d^2y}{dx^2}$, as functions of x; and this, combined with the other two, gives $\frac{d^3y}{dx^3}$, and so on to any number of equations.

Let y be such a function of x that

$$y^2 - 2\,mxy + x^2 - a^2 = 0 \ldots\ldots\ldots\ldots\text{(1.)}$$

It is proposed to determine its differential co-efficients.

By a first differentiation

$$(y - mx)\,dy - (my - x)\,dx = 0,$$

$$\text{and } \frac{dy}{dx} = \frac{my - x}{y - mx} \ldots\ldots\ldots\ldots\ldots\ldots\text{(2.)}$$

Again, by differentiating,

$$\frac{d^2y}{dy^2} = \frac{(1 - m^2)x}{(y - mx)^2} \cdot \frac{dy}{dx} - \frac{(1 - m^2)y}{(y - mx)^2} \ldots\ldots\text{(3.)}$$

and, substituting for $\frac{dy}{dx}$ its value,

$$\frac{d^2y}{dx^2} = -(1 - m^2)\,\frac{y^2 - 2\,mxy + x^2}{(y - mx)^3} = \frac{-(1 - m^2)a^2}{(y - mx)^3}\text{(4.)}$$

If we take the differentials of both sides of equation (3), and consider $\frac{dy}{dx}$, $\frac{d^2y}{dx^2}$, as functions of x, we shall obtain

$$\frac{d^3y}{dx^3} = \mathrm{P}\,\frac{d^2y}{dx^2} + \mathrm{Q}\,\frac{dy}{dx} + \mathrm{R} \ldots\ldots\ldots\ldots\ldots\text{(5.)}$$

Here P, Q, R, denote expressions composed of y and x. By substituting for $\frac{d^2y}{dx^2}$ and $\frac{dy}{dx}$ their values as given by equations (4) and (2), there will be obtained the value of $\frac{d^3y}{dx^3}$, in terms of x and y.

52. The equations which may be deduced by differentiation from a proposed equation are called *fluxional* or *differential* equations, and the equation from which they have been deduced is called the *primitive* equation. The equation which gives the value of $\frac{dy}{dx}$ is said to be of the *first order*, and that which involves $\frac{d^2y}{dx^2}$ is of the *second order*, and so on for the higher orders.

Thus, the primitive equation being

$$y^2 - 2mxy + x^2 - a^2 = 0,$$

we have found, for the differential equation of the first order,

$$\frac{dy}{dx} - \frac{my - x}{y - mx} = 0\,;$$

and that of the second order,

$$\frac{d^2y}{dx^2} - \frac{(1 - m^2)}{y - mx}\,\frac{dy}{dx} + \frac{(1 - m^2)y}{(y - mx)^2} = 0,$$

equivalent to $\frac{d^2y}{dx^2} + (1 - m^2)\,\frac{y^2 - 2mxy + x^2}{(y - mx)^3} = 0.$

53. Differential equations of all orders hold true simultaneously with the primitive from which they have been derived, therefore any combination of them will also hold true; and whatever number of values the function y has (in the preceding example it has two), the differential co-efficients into which y enters will have the same number.

It has appeared (art 15) that in functions of a certain form the constants they contain vanish from their differentials. A like remark applies to differential equations. Thus, if $y^2 = ax + b$ be a primitive equation, in which a and b are constants, the differential equation is $2ydy = adx$; and this belongs to every particular equation which can be formed from the primitive, by giving all possible values to b. The constant a may also be made to disappear by putting the equation under this form,

$$\frac{y^2}{x} = a + \frac{b}{x}\,;$$

for this by differentiation gives

$$\frac{2xydy - y^2dx}{x^2} = \frac{-bdx}{x^2},$$

$$\text{and } 2xydy - (y^2 - b)\,dx = 0\,;\text{ or } \frac{dy}{dx} = \frac{y^2 - b}{2xy}.$$

This equation expresses a relation which subsists between the quantities x, y, $\frac{dy}{dx}$, independently of any particular value of the constant a.

The very same equation will be obtained by eliminating, by the ordinary process (ALGEBRA, sect. 7), a from the two equations

$$y^2 = ax + b,\ 2ydy = adx.$$

If the constant quantity which is eliminated is not of the first degree in the proposed equation, the result will contain powers of the co-efficient $\frac{dy}{dx}$ higher than the first. For example, let the equation be

$$y^2 - 2ay + x^2 = a^2\,;$$

then, by differentiating,

$$2ydy - ady + xdx = 0,$$

$$\text{hence } a = \frac{ydy + xdx}{dy}.$$

This value of a being substituted in the proposed equation, we obtain, after due reduction,

$$(x^2 - 2y^2)\,\frac{dy^2}{dx^2} - 4xy\frac{dy}{dx} - x^2 = 0\,;$$

an equation that expresses a relation between x, y, $\frac{dy}{dx}$, which is independent of any particular value of a.

By resolving the equation in respect of a, we find

$$a = -y \pm \sqrt{2y^2 + x^2}\,;$$

and hence, the constant a forming a term by itself, it disappears by differentiation, and we have

$$dy \pm \frac{2ydy + xdx}{\sqrt{2y^2 + x^2}} = 0,$$

an equation which, being from the radical sign, will be identical with the former.

54. Any number of constants whatever may be made to disappear by repeating the process of differentiation as often as there are quantities to be eliminated; for example, let the equation be $y^2 = m\,(a^2 - x^2)$; by a first differentiation $y\,\frac{dy}{dx} = -mx$; taking the differentials a se-

cond time, we get $y\frac{d^2y}{dx^2}+\frac{dy^2}{dx^2}=-m$. This value of $-m$ being substituted in the former equation, it becomes

$$y\frac{dy}{dx}-x\frac{dy^2}{dx^2}-xy\frac{d^2y}{dx^2}=0,$$

a result which is independent of both a and m.

Of Vanishing Fractions.

55. When the numerator and denominator of a fraction are such functions that, by giving a particular value to their variable, they both become $=0$ at the same time, the fraction is then called a *vanishing* fraction. The fraction $\frac{x^2-a^2}{x-a}$ is of this kind; for when $x=a$, the numerator and denominator both vanish, and the fraction takes the form $\frac{0}{0}$, from which we can draw no conclusion as to its true value, although it be evident that the fraction has then a determinate value; for

$$\frac{x^2-a^2}{x-a}=\frac{(x+a)(x-a)}{x-a}=x+a;$$

and when $x=a$, its true value is as $a+a=2a$.

It appears that the above fraction has taken the peculiar form $\frac{0}{0}$ when $x=a$, from the circumstance of its having the factor $x-a$ in the numerator and denominator. The same is true of this other fraction,

$$\frac{x^3-x^2a-xa^2+a^3}{ax-a^2},$$

which takes form $\frac{0}{0}$ when $x=a$. The numerator and denominator have a common divisor, $x-a$; when freed from this, it becomes $\frac{x^2-a^2}{a}$; when $x=a$, this fraction becomes $\frac{0}{a}$, which is truly $=0$. Again, this fraction $\frac{ax-a^2}{x^2-2ax+a^2}$, which has the same property when $x=a$, by reason of the common factor $x-a$, when freed from the factor is $\frac{a}{x-a}$. Thus when $x=a$ becomes $\frac{a}{0}$, that is, the value is infinite. In these cases the common factor is obvious; but it is not so always. Take this as an example, $\frac{1-\sin x+\cos x}{\sin x+\cos x-1}$; when x is a quadrant, or $=\frac{1}{2}\pi$, this fraction becomes $\frac{0}{0}$. For its true value in this case, see ex. 4 of art. 57.

56. When the terms of the fraction are algebraic functions, their greatest common measure may be found by an elementary operation in ALGEBRA (art. 20), and the fraction disengaged from it by division. A more simple and general solution may, however, be obtained from the differential calculus.

Let $\frac{P}{Q}$ denote a fraction, the terms of which are functions of x that vanish when $x=a$, some given quantity. Suppose now that x becomes $x+h$, then, by Taylor's theorem, the fraction will become

$$\frac{P+\frac{dP}{dx}h+\frac{d^2P}{dx^2}\frac{h^2}{1\,.\,2}+\frac{d^3P}{dx^3}\frac{h^3}{1\,.\,2\,.\,3}+,\ \&c.}{Q+\frac{dQ}{dx}h+\frac{d^2Q}{dx^2}\frac{h^2}{1\,.\,2}+\frac{d^3Q}{dx^3}\frac{h^3}{1\,.\,2\,.\,3}+,\ \&c.}.$$

By hypothesis, when $x=a$, then P and Q both vanish; therefore, leaving them out of the expression, and putting P′, P″, P‴, &c. to denote the differential co-efficients of P in the numerator, and Q′, Q″, Q‴, &c. those of Q in the denominator, and dividing the terms by h, the fraction will be expressed by

$$\frac{P'+\frac{1}{2}P''h+\frac{1}{6}P'''h^2+,\ \&c.}{Q'+\frac{1}{2}Q\,h+\frac{1}{6}Q'''h^2+,\ \&c.}.$$

When $h=0$, this expression becomes $\frac{P'}{Q'}$; and when a is put in this fraction instead of x, the result will be the true value of $\frac{P}{Q}$; for it is manifestly the same thing to suppose, first, that x becomes $x+h$, and then that $x=a$ and $h=0$, as to suppose at once that $x=a$.

If it happen that one of the two quantities, P′, Q′, becomes $=0$ when a is substituted instead of x, then the fraction $\frac{P}{Q}$ will be $=0$, or infinite, according as the vanishing quantity is the numerator or denominator; if both become $=0$ at once, then, leaving them out, the expression becomes, by reduction,

$$\frac{P''+\frac{1}{3}P'''h+,\ \&c.}{Q''+\frac{1}{3}Q'''h+,\ \&c.};$$

and making $h=0$, it become $\frac{P''}{Q''}$, which, putting a instead of x, will be the value of the fraction $\frac{P}{Q}$, and so on.

57. Hence we have this rule: To find the fraction $\frac{P}{Q}$ in the particular case of $x=a$, supposing that P and Q are both reduced to 0 by this supposition. Divide the differential co-efficient of the numerator by that of the denominator; let the result be $\frac{P'}{Q'}$, in which make $x=a$; then, if this expression does not become $\frac{0}{0}$, it is the value sought; but if it takes the form $\frac{0}{0}$, treat the fraction $\frac{P'}{Q'}$ in all respects like the original fraction, and deduce from it a new fraction $\frac{P''}{Q''}$, and proceed in this way until an expression be found which does not become $\frac{0}{0}$ when a is put for x; and the first expression that is found having this property is the value sought.

Ex. 1. The sum of the geometrical series

$$1+x+x^2+x^3\ldots+x^{n-1}\text{ to }n\text{ terms}$$

is $\frac{x^n-1}{x-1}$. Find its value when $x=1$.

In this case, $P=x^n-1$, $Q=x-1$; hence we deduce $\frac{dP}{dx}=nx^{n-1}=P'$; $\frac{dQ}{dx}=1=Q$, $\frac{P'}{Q'}=nx^{n-1}$; when $x=1$, the fraction $\frac{P'}{Q'}=n$, the value of the sum of the series, as is manifest.

Ex. 2. Let the fraction be $\frac{ax^2+ac^2-2acx}{bx^2-2bcx+bc^2}=\frac{P}{Q}$, which becomes $\frac{0}{0}$ when $x=c$, to find its value. In this case $\frac{dP}{dx}=2ax-2ac=P'$; $\frac{dQ}{dx}=2bx-2bc=Q'$;

$$\frac{P'}{Q'} = \frac{2ax - 2ac}{2bx - 2bc} = \frac{ax - ac}{bx - bc}.$$

Making $x = c$, this fraction becomes $\frac{0}{0}$, therefore, proceeding as before,

$$\frac{d^2P}{dx^2} = 2a = P'', \; \frac{d^2Q}{dx^2} = 2b = Q'', \; \frac{P''}{Q''} = \frac{a}{b};$$

hence it appears that when $x = c$, the value of the fraction is $\frac{a}{b}$.

Ex. 3. The fraction $\frac{a^x - b^x}{x}$ becomes $\frac{0}{0}$ when $x = 0$. Find its value then. In this case,

$$\frac{dP}{dx} = \text{l.}\,(a)\, a^x - \text{l.}\,(b)\, b^x = P'; \; \frac{dQ}{dx} = 1 = Q'.$$

When $x = 0$, $\frac{P'}{Q'}$ becomes $\text{l.}\,(a) - \text{l.}\,(b) = \text{l.}\,\frac{a}{b}$, the value required.

Ex. 4. Let the fraction be $\frac{1 - \sin x + \cos x}{\sin x + \cos x - 1}$, which becomes $\frac{0}{0}$ when $x = \frac{1}{2}\pi$. Here

$$\frac{dP}{dx} = -\cos x - \sin x = P'; \; \frac{dQ}{dx} = \cos x - \sin x = Q';$$

$$\frac{P'}{Q'} = \frac{-\cos x - \sin x}{\cos x - \sin x}.$$

When $x = \frac{1}{2}\pi$, a quadrant, then $\cos x = 0$, and $\sin x = 1$; the value of the proposed fraction is therefore $\frac{-1}{-1} = 1$.

Ex. 5. Let the fraction be $\frac{a^{a-n} - x^{x-n}}{a - x}$; to find its value when $x = a$. In this case $P = a^{a-n} - x^{x-n}$, $Q = a - x$.

$$P' = \frac{dP}{dx} = -x^{x-n}\left\{\text{l.}\,x + \frac{x-n}{x}\right\};$$

$$Q' = \frac{dQ}{dx} = -1,$$

$$\frac{P'}{Q'} = x^{x-n}\left\{\text{l.}\,x + \frac{x-n}{x}\right\}:$$

making $x = a$, we have $a^{a-n}\left\{\text{l.}\,a + \frac{a-n}{a}\right\}$ for the value required.

58. The rule of last article will not apply when Taylor's theorem fails to give the developments of the functions P, Q, in the case when $x = a$. When this happens, we may substitute $a + h$ instead of x in the fraction $\frac{P}{Q}$, and expand the numerator and denominator into ascending series, which proceed by the powers of h; we shall then have

$$\frac{Ah^\alpha + Bh^\beta +, \&c.}{A'h^{\alpha'} + B'h^{\beta'} +, \&c.}$$

instead of the proposed fraction. If in this result we suppose $h = 0$, we shall have the value of the fraction $\frac{P}{Q}$ when $x = a$. Now there are here three cases; viz. $\alpha > \alpha'$, $\alpha = \alpha'$, and $\alpha < \alpha'$. In the first case, we may write the expression thus:

$$\frac{Ah^{\alpha - \alpha'} + Bh^{\beta - \alpha} +, \&c.}{A' + B'h^{\beta - \alpha'} +, \&c.};$$

Under this form, it is manifest that as long as α is greater than α', the supposition of $h = 0$ will make the fraction equal to nothing, and that it will become $\frac{A}{A'}$ when $\alpha = \alpha'$; but when $\alpha < \alpha'$, we write the expression thus:

$$\frac{A + Bh^{\beta - \alpha} +, \&c.}{A'h^{\alpha' - \alpha} + B'h^{\beta' - \alpha} +, \&c.};$$

and by the supposition of $h = 0$, this result becomes infinite. In all cases the true value depends on the first term alone of each series.

59. The following rule extends to all fractions which can occur under the indeterminate form $\frac{0}{0}$.

Take the first term of each of the series which express the development of the numerator and denominator when x = a + h; *reduce the resulting fraction to its most simple form, and then make* h = 0.

The fraction $\frac{(x^2 - a^2)^{\frac{3}{2}}}{(x - a)^{\frac{3}{2}}}$, whose value cannot be found by differentiation, when $x = a$ becomes by this method

$$\frac{(2ah + h^2)^{\frac{3}{2}}}{h^{\frac{3}{2}}} = (2a + h)^{\frac{3}{2}},$$

when x is changed into $x + h$; making now $h = 0$, we have its true value $(2a)^{\frac{3}{2}}$.

This last rule will sometimes be preferable to the former, by differentiation, even when that process is applicable. For example, four successive differentiations must be performed on the numerator and denominator of this fraction,

$$\frac{x^3 + 4ax^2 + 7a^2 x - 2a^3 - 2a^2 \sqrt{2ax - a^2}}{x^2 - 2ax - a^2 + 2a \sqrt{2ax - x^2}},$$

in order to find its true value when $x = a$; by writing $a + h$ instead of x, it becomes

$$\frac{2a^3 - 2a^2 h - ah^2 + h^3 - 2a^2 \sqrt{a^2 + 2al}}{-2a^2 + h^2 + 2a \sqrt{a^2 - h^2}}$$

and reducing the radical quantities into series, we have

$$\sqrt{a^2 + 2ah} = a + h - \frac{h^2}{2a} + \frac{h^3}{2a^2}, - \frac{5h^4}{8a^3}, +, \&c.$$

$$\sqrt{a^2 - h^2} = a - \frac{h^2}{2a} - \frac{h^4}{8a^3} -, \&c.$$

By substituting these series in the fraction, and putting $h = 0$, we obtain $-5a$ for the value sought.

Of the greatest and least Values of a Function.

60. In supposing that a function changes its value, we may assume that the variable increases continually from 0 to infinity, either positively or negatively. To get distinct notions, it may be convenient to suppose that the variable increases or decreases by successive equal differences. The function however may not increase or decrease continually along with its variable. It may first increase to a certain magnitude, and afterwards decrease; or it may decrease and afterwards increase; or it may alternately increase and decrease several times. We may represent the variable x by the abscissa of a curve, and the function y by the corresponding ordinate. The curve, from

its nature, may recede continually from its axis, like the parabola and hyperbola; or it may first recede from and afterwards approach to the axis, like the circle and ellipse; or it may be sinuous, alternately approaching and receding.

When a variable function, by a continual change in its magnitude, first increases and afterwards decreases, there will be one value of the function which will be greater than those which immediately preceded it, and also greater than those which immediately follow it. In this state the value of the function is the greatest possible, at least within certain limits on each side of that extreme value; and then it is said to be a *maximum*. On the other hand, if a function, by a continual change in its value, first decreases, until it be reduced to a certain magnitude, and afterwards increases, it is said to be a *minimum*, when it is just changing from the state of a decreasing to that of an increasing quantity.

A variable function may have several values, each of which will be a *maximum* or *minimum*, according to the definition. *The essential character of a maximum consists in its being greater than the values which preceded and which follow it; and that of a minimum in being less than the preceding and following values.* So that as many changes as there may be from increase to decrease, or the contrary, so many *maxima* and *minima* there will be.

61. Before proceeding farther, it will be convenient to establish this principle. In a series of the form

$$ph + qh^2 + rh^3 + sh^4 +, \&c.$$

in which h is indeterminate, and independent of p, q, r, &c. such a value may be given to h, that any term shall exceed the amount of all that follow it. For, putting the series under this form,

$$h\,(p + qh + rh^2 + sh^3 +, \&c.);$$

by supposing h to decrease, $qh + rh^2 + sh^3 +$, &c. may become less than any assignable quantity, and therefore less than p; consequently, $qh^2 + rh^3 + sh^4 +$, &c. may be less than ph, in any ratio of inequality. In the same way it will appear that $rh + sh^2 +$, &c. may be less than q, and $rh^3 + sh^4 +$, &c. less than qh^2, and so on. Hence it follows, that in the series $ph + qh^2 + rh^3 + sh^4 +$, &c. h may have such a value that the amount of all the terms beginning with any assigned term shall have the sign of that term, $+$ if it be $+$, and $-$ if it be $-$.

62. Let y denote any function which may become a *maximum* or *minimum* when its variable has attained some particular value; then, if $x - h$ and $x + h$ be substituted successively in the function instead of x, the two results must be both less than the maximum value, and both greater than the minimum value. Denoting now the value of the function which corresponds to $x - h$ by ${}_1y$, and the value which corresponds to $x + h$ by y_1, we have, by Taylor's theorem,

$${}_1y = y - \frac{dy}{dx}h + \frac{d^2y}{dx^2}\frac{h^2}{1.2} - \frac{d^3x}{dx^3}\frac{h^3}{1.2.3} +, \&c.$$

$$y_1 = y + \frac{dy}{dx}h + \frac{d^2y}{dx^2}\frac{h^2}{1.2} + \frac{d^3y}{dx^3}\frac{h^3}{1.2.3} +, \&c.$$

Now, it is impossible that ${}_1y$ and y_1 can at the same time be both less or both greater than y, if the co-efficient $\frac{dy}{dx}$ be not $= 0$; for if it have some value different from *zero*, then such a value may be given to h that $\frac{dy}{dx}h$ shall exceed in any given ratio of inequality all the terms which follow it, and one of the two series beginning with $\mp \frac{dy}{dx}h$ will be a positive quantity and the other negative; and if this were true, y would be of an intermediate magnitude between ${}_1y$ and y_1, which cannot be, when it is a *maximum* or *minimum*. Therefore, in order that y may be a *maximum* or *minimum*, we must have $\frac{dy}{dx} = 0$, and then, in the expressions

$${}_1y = y + \frac{d^2y}{dx^2}\frac{h^2}{1.2} - \frac{d^3y}{dx^3}\frac{h^3}{1.2.3} +, \&c.$$

$$y_1 = y + \frac{d^2y}{dx^2}\frac{h^2}{1.2} + \frac{d^3y}{dx^3}\frac{h^3}{1.2.3} +, \&c.$$

such a value may be given to h as shall make ${}_1y$ and y_1 both less than y in the case of a *maximum*, or both greater in that of a *minimum*.

It may, however, happen that the value of x which makes $\frac{d^2y}{dx^2} = 0$ shall also make $\frac{d^2y}{dx^2} = 0$, so that we have

$${}_1y = y - \frac{d^3y}{dx^3}\frac{h^3}{1.2.3} + \frac{d^4y}{dx^4}\frac{h^4}{1.2.3.4} -, \&c.$$

$$y_1 = y + \frac{d^3y}{dx^3}\frac{h^3}{1.2.3} + \frac{d^4y}{dx^4}\frac{h^4}{1.2.3.4} +, \&c.$$

Then the function cannot be a maximum or minimum, unless the same value of x make $\frac{d^3y}{dx^3} = 0$, and give a finite value for $\frac{d^4y}{dx^4}$

63. On the whole, we have this rule, to determine the maximum or minimum value of y, a function of x.

Make the differential co-efficient $\frac{\mathrm{dy}}{\mathrm{dx}} = 0$: *Find the value of* x, *and substitute it in* $\frac{\mathrm{d^2y}}{\mathrm{dx^2}}$; *and if the result be negative, the function is a* maximum; *but if it be positive, the function is a* minimum. *And if it be* $= 0$, *then put* $\frac{\mathrm{d^3y}}{\mathrm{dx^3}} = 0$, *and find* x, *and substitute it in* $\frac{\mathrm{d^4y}}{\mathrm{dx^4}}$, *and draw the same conclusions from the signs as before, and so on.*

The rule for determining a maximum or minimum of a function was first given correctly by Maclaurin, in his FLUXIONS, chap. ix.

64. We shall now apply the theory to the resolution of problems, of which there may be an endless variety, and many highly interesting.

Ex. 1. To determine whether the function $u = 2ax - x^2$ has a *maximum* or *minimum* value.

In this case the differential co-efficient $\frac{du}{dx} = 2\,(a - x)$, which being put $= 0$, we have $x = a$. The second differential co-efficient $\frac{d^2u}{dx^2} = 2$, a negative quantity, therefore the function has a maximum value (art. 63), viz. when $x = a$; and that value is $u = a^2$, as is indeed evident from the nature of the function.

Ex. 2. Let $u = x^2 + 3x + 2$; then $\frac{du}{dx} = 2x + 3$. This put $= 0$, gives $x = -\frac{3}{2}$. Again, $\frac{d^2u}{dx^2} = 2$, a positive quantity, therefore the function is a *minimum* when $x = -\frac{3}{2}$. In that case $u = -\frac{1}{4}$.

Ex. 3. Let $u = x^3 - 15\,x^2 + 56x - 60$. Here

$$\frac{du}{dx} = 3x^2 - 30\,x + 56,\quad \frac{d^2u}{dx^2} = 6x - 30.$$

The equation $\frac{du}{dx} = 3x^2 - 30x + 56 = 0$ being resolved, we find $x = \frac{15 \pm \sqrt{57}}{3}$. Making $x = \frac{15 \pm \sqrt{57}}{3}$, we find $\frac{d^2u}{dx^2} = 6x - 30 = \pm 2\sqrt{57}$. Hence it appears that the function has a *minimum*, and also a *maximum* value; the former corresponding to $x = \frac{15 + \sqrt{57}}{3}$, and the latter to $x = \frac{15 - \sqrt{57}}{3}$.

If $x = \frac{15 + \sqrt{57}}{3}$, $u = -30 - \frac{38}{9}\sqrt{57}$, a *minimum.*

If $x = \frac{15 - \sqrt{57}}{3}$, $u = -30 + \frac{38}{9}\sqrt{57}$, a *maximum.*

Ex. 4. Let $u = x^5 - 5x^4 + 5x^3 + 1$;

then $\frac{du}{dx} = 5x^4 - 20x^3 + 15x^2 = 5x^2(x^2 - 4x + 3)$;

$$\frac{d^2u}{dx^2} = 20x^3 - 60x^2 + 30x = 10x(2x^2 - 6x + 3).$$

The equation $\frac{du}{dx} = 5x^2(x^2 - 4x + 3) = 0$,

gives four values of x, viz. $x = 3$, $x = 1$, the other two are $= 0$.

These being substituted in $\frac{d^2u}{dx^2}$, show that the function has a *maximum* and *minimum:*

when $x = 3$, $u = -26$, a *minimum ;*
$x = 1$, $u = 2$, a *maximum ;*

when $x = 0$, then $\frac{d^2u}{dx^2}$ vanishes, therefore there is neither *maximum* or *minimum* in this case.

Ex. 5. To determine the *maxima* and *minima* values of the function $y = x^x$; we have found (art. 24, ex. 2), that

$$\frac{dy}{dx} = x^x(1 + \text{l.}\,x);$$

and hence $\frac{d^2y}{dx^2} = x^x\left\{\frac{1}{x} + (1 + \text{l.}\,x)^2\right\}$;

The function x^x cannot be $= 0$; we must therefore put $1 + \text{l.}\,x = 0$;

$$\text{hence l.}\,x = -1, \text{ and } x = e^{-1} = \frac{1}{e}.$$

This value of x, substituted in the second differential coefficient, makes

$$\frac{d^2u}{dx^2} = \left(\frac{1}{e}\right)^{\frac{1}{e}} \cdot e, \text{ a positive quantity;}$$

therefore, when $x = \frac{1}{e}$, $x^x = \left(\frac{1}{e}\right)^{\frac{1}{e}}$, a *minimum.*

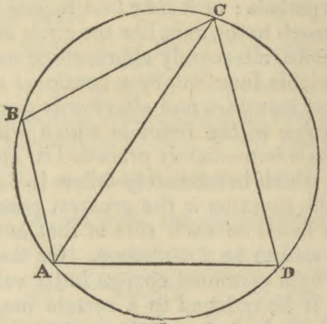
Ex. 6. To find the greatest space that can be enclosed by four given straight lines:

Let the given lines be $AB = a$, $BC = b$, $CD = e$, $DA = f$: Let $x =$ angle B, $v =$ angle D, $y =$ the area ABCD: Draw the diagonal AC.

By trigonometry, $a^2 + b^2 - 2ab \cos x = AC^2$,
$e^2 + f^2 - 2ef \cos v = AC^2$;

Hence, $2ab \cos x - 2ef \cos v = a^2 + b^2 - e^2 - f^2$.........(1)

Fig. 1.



And because trian. $ABC = \frac{1}{2}ab \sin x$; trian. $ADC = \frac{1}{2}ef \sin v$,

therefore, $y = \frac{1}{2}ab \sin x + \frac{1}{2}ef \sin v$.........................(2)

This last equation by differentiation gives, by the nature of a maximum,

$\frac{dy}{dx} = \frac{1}{2}ab \cos x + \frac{1}{2}ef \frac{dv}{dx} \cos v = 0$.....................(3)

By differentiating equation (1), we find

$$ab\,dx \sin x - ef\,dv \sin v = 0;$$

and hence $ef\frac{dv}{dx} = -ab\frac{\sin x}{\sin v}$:

Therefore, from eq. (3), $ab\left\{\cos x + \frac{\sin x \cos v}{\sin v}\right\} = 0$;

and hence $\sin v \cos x + \cos v \sin x = 0$;

that is (ALGEBRA, art. 239), $\sin(x+v) = 0$, and $x + v = \pi$.

Thus it appears that the opposite angles B, D must together make two right angles; therefore the figure will be a *maximum* when it is inscribed in a circle; and since in this case

$$\cos x = -\cos v, \ \sin x = \sin v;$$

from equations (1) and (2),

$$2(ab+ef)\cos x = a^2 + b^2 - e^2 - f^2,$$
$$2(ab+ef)\sin x = 4y.$$

By squaring both sides of these equations, and adding, and observing that $\cos^2 x + \sin^2 x = 1$, we have

$$4(ab+ef)^2 = (a^2+b^2-e^2-f^2)^2 + 16y^2,$$

and $16y^2 = 4(ab+ef)^2 - (a^2+b^2-e^2-f^2)^2$.

The right-hand side of this formula admits of being resolved into these two factors, viz.

$$2ab + 2ef + a^2 + b^2 - e^2 - f^2 = (a+b)^2 - (e-f)^2,$$
$$2ab + 2ef - a^2 - b^2 + e^2 + f^2 = (e+f)^2 - (a-b)^2;$$

and these again admit of this further resolution,

$$(a+b+e-f)\,(a+b-e+f),$$
$$(e+f+a-b)\,(e+f-a+b);$$

If we now put $s = \frac{1}{2}(a+b+e+f)$,

we have $a+b+e-f = 2(s-f)$,
$a+b-e+f = 2(s-e)$,
$e+f+a-b = 2(s-b)$,
$e+f-a+b = 2(s-a)$.

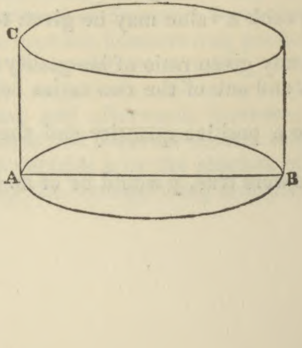
Hence $16y^2 = 16(s-a)(s-b)(s-e)(s-f)$;

and $y = \sqrt{(s-a)(s-b)(s-e)(s-f)}$.

We have now found by the calculus an elegant geometrical theorem.

Ex. 7. To determine the dimensions of a cylindric measure, open at top, which shall contain a given quantity of grain, liquor, &c. under the least internal superficies.

Fig. 2.



Di
Me

Let $x = AB$ be the diameter of the base, $v = AC$ its depth, π the number 3·1416 (viz. half the circumference of a circle whose rad. = 1), and c the content of the cylinder. By GEOMETRY, the area of the base $= \frac{\pi x^2}{4}$, and its circumference $= \pi x$, and the internal surface of the cylinder $= v\pi x$. Now, the content of the cylinder $c = \frac{\pi x^2 v}{4}$; and therefore $v = \frac{4c}{\pi x^2}$; therefore the internal surface $= \frac{4c}{x}$; and putting y for the whole inside surface of the measure,

$$y = \frac{\pi x^2}{4} + \frac{4c}{x},$$

$$\text{therefore, } \frac{dy}{dx} = \frac{\pi x}{2} - \frac{4c}{x^2} = 0;$$

$$\frac{d^2y}{dx^2} = \frac{\pi}{2} + \frac{8c}{x^3}.$$

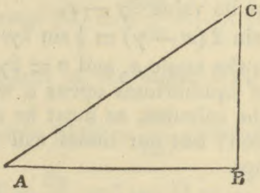
The first of these equations gives

$$\pi x^3 = 8c = 2\pi x^2 v, \text{ and } x = 2v;$$

hence the diameter of the base must be twice the depth: The second differential co-efficient being a positive quantity, shows the surface to be a *minimum.*

Ex. 8. A candle stands on a horizontal table, directly over a point at a given distance from a small object on the table; what ought to be the height of the flame when the object is illuminated the most possible.

Fig. 3.



Let A be the object on the table, B the point under the candle, and C the flame, considered as condensed at a point. The intensity of the illumination on the object A depends on its distance from C, and on the angle which the rays make with the surface (supposed to be horizontal). By the principles of optics, the intensity at different distances, the angle of obliquity being the same, will be inversely as the square of the distance; and with different degrees of obliquity, the distance being the same, as the sine of the angle which the rays make with the surface. Therefore the intensity, as depending on both obliquity and distance, will be expressed by

$$\frac{1}{AC^2} \sin CAB = \frac{BC}{AC^3}.$$

Put $a = AB$, $x = \sin CAB$, and let y denote the illuminating power on the surface at A; then

$$y = \frac{BC}{AC} \times \frac{AB^2}{AC^2} \times \frac{1}{AB^2} = \frac{\sin x \cos^2 x}{a^2},$$

$$\frac{dy}{dx} = \left\{ \cos^3 x - 2 \sin^2 x \cos x \right\} \frac{1}{a^2} = 0;$$

hence, $2 \sin^2 x \cos x = \cos^3 x$,

$$\text{and } \frac{\sin^2 x}{\cos^2 x} = \frac{1 - \cos 2x}{1 + \cos 2x} = \tfrac{1}{2}, \text{ and } \cos 2x = \tfrac{1}{3}.$$

By the trigonometrical tables, $2x = 70° 32'$, and $x = 35° 16'$; this gives $BC = AB \times .71$ nearly: so that the height of the flame must be about $\frac{7}{10}$ of the distance AB.

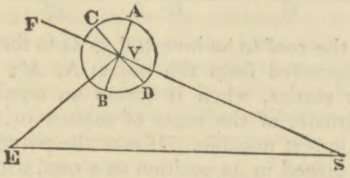
Ex. 9. To find the position of the planet Venus in respect of the earth and sun when her light is the greatest.

Direct Method.

The planet does not appear brightest when her disc is perfectly round; she is then too remote to produce that effect; and besides, she is seen in the direction of the sun. In her inferior conjunctions her crescent is too narrow, almost the whole illuminated part being turned towards the sun. It is therefore in some intermediate position, which is to be determined, that she is brightest.

Let S be the sun, E the earth, and ACBD Venus, ADB its illuminated hemisphere which is turned towards the sun, and CBD its hemisphere towards the earth: produce S V to F.

Fig. 4.



The portion of the illuminated surface turned towards the earth is contained between two planes DV, BV, perpendicular to the plane EVS; and this surface will manifestly be projected into a crescent, the breadth of which is the versed sine of the angle BVD, which is equal to EVF, because if BVE be added to both, each is a right angle. Now the area of the crescent is always as its breadth; therefore, the whole disk being taken as an unit, the illuminated part of it will be expressed by the versed sine of the angle EVF, or by $1 + \cos EVS$.

Again, the brightness of the planet at different distances is inversely as the square of the distance; therefore the brightness depending on its position in respect of the sun and its distance from the earth jointly, will be proportional to $\frac{1 + \cos EVS}{EV^2}$.

Let $a = ES$ the distance of the earth from the sun,
$b = VS$ the distance of Venus from the sun,
$x = VE$ the distance of Venus from the earth;

$$\text{Then, } \cos EVS \frac{x^2 + b^2 - a^2}{2bx},$$

$$\text{and } 1 + \cos EVS = \frac{x^2 + 2bx + b^2 - a^2}{2bx}.$$

$$= \frac{(x + b + a)(x + b - a)}{2bx};$$

therefore, putting y to denote the brightness of the planet,

$$y = \frac{(x + b + a)(x + b - a)}{2bx^3} \text{ a } maximum;$$

and this, by differentiation, gives

$$\frac{dy}{dx} = \frac{(x + b + a)(x + b - a)}{2bx^3} \left\{ \frac{1}{x + b + a} + \frac{1}{x + b - a} - \frac{3}{x} \right\} = 0;$$

$$\text{and hence, } \frac{3(a^2 - b^2) - 4bx - x^2}{2bx^4} = 0;$$

$$x^2 + 4bx = 3(a^2 - b^2),$$

$$x = \pm \sqrt{3a^2 + b^2} - 2b.$$

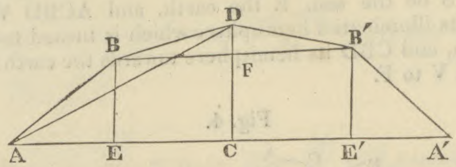
The negative value of x is not applicable, and we have

$$x = \sqrt{3a^2 + b^2} - 2b.$$

In numbers, $a = 10000$, $b = 7233$, therefore $x = 4304$, the angles $E = 39° 43' 30''$, $V = 117° 55' 20''$, $S = 22° 21' 10''$.

Ex. 10. Let ABDB′A′ be a kirb roof supported by four rafters AB, BD, DB′, B′A′, two and two of which are equal, viz. AB = A′B′, and BD = B′D, and all perfectly free to turn about the points A, B, D, B′, A′, as joints. Suppose also that AA′ the span, and DC the height of the roof, are given, and that AB has to BD a given ratio. Determine the position of the rafters when by their weight they form an equilibrium.

Fig. 5.



Suppose the roof to be inverted so as to form a polygon hanging suspended from the points A, A′; by a known principle in statics, when it forms an equilibrium, the centre of gravity of the mass of matter in the polygon will be the lowest possible. If now the polygon were reversed and placed in its position as a roof, without changing the angles at the joints, the equilibrium would not be disturbed, and in this position the centre of gravity would be the highest possible.

Draw a line from B to B′, which will be parallel to AA′; and draw the perpendiculars BE, B′E′. Put the angle BAC = B′A′C = x, DBF = DB′F = v; let the given ratio of AB to BD be that of a given number m to a given number n; these numbers may represent the length, also the weight, of the rafters, which may be supposed placed in their centres of gravity, or middle of the beams.

By trigonometry, BE = m sin x, DF = n sin v, therefore DC = $m \sin x + n \sin v$; and, by statics, the height of the centre of gravity of AB, also of A′B′, above AA will be $\frac{1}{2}$ BE = $\frac{1}{2} m \sin x$, and the height of the centre of gravity of BD, also of B′D, will be $\frac{1}{2}$ (BE + DC) = $m \sin x + \frac{1}{2} n \sin v$; and since the distance of the common centre of gravity of all the beams from AA′ will be found by multiplying the distance of each centre by the mass, supposed placed at that centre, and adding the results into one sum, and dividing by the sum of all the masses; the height of the centre of gravity of the whole system of beams above AA′ will be

$$\frac{m^2 \sin x + n\,(2\,m \sin x + n \sin v)}{2\,(m+n)}.$$

Let this height be denoted by y; then, rejecting the constant denominator $2\,(m+n)$,

$y = (m^2 + 2\,mn) \sin x + n^2 \sin v$, a maximum;

and since AC, half the span of the roof, is a given quantity, we have

$m \cos x + n \cos v =$ AC, *a constant.*

From the first equation,

$$\frac{dy}{dx} = (m^2 + 2\,mn) \cos x + n^2 \cos v \frac{dv}{dx} = 0;$$

and from the second,

$$m \sin x + n \sin v \frac{dv}{dx} = 0; \text{ hence } \frac{dv}{dx} = -\frac{m \sin x}{n \sin v}.$$

This value of $\frac{dv}{dx}$ being substituted in the value of $\frac{dy}{dx}$, we obtain

$$(m^2 + 2\,mn) \cos x - \frac{mn \cos v \sin x}{\sin v} = 0;$$

and from this again,

$$\frac{\tan x}{\tan v} = \frac{m}{n} + 2 \ldots\ldots\ldots\ldots\ldots\ldots (1.)$$

This formula expresses a property of all roofs made of four beams, which are equal two and two, when by their position they form an equilibrium.

Join AD, and put $\gamma =$ angle DAC which is known, because $\tan \gamma = \frac{\text{DC}}{\text{AC}}$. The angle BAD $= x - \gamma$, and BDA $= \gamma - v$. Now, in the triangle ABD, sin A : sin D = DB : BA, that is, $\sin (x - \gamma) : \sin (\gamma - v) = n : m$; therefore,

$$\frac{\sin (x - \gamma)}{\sin (\gamma - v)} = \frac{n}{m} \ldots\ldots\ldots\ldots (2.)$$

These equations (1), (2), determine the angles x, v, when the ratio of AB to BD is given; from their form, the angles may be easily found by trials in the trigonometrical tables. The elimination of one of the angles would produce an equation of the fourth degree; for this reason, the method of trials is the best way of proceeding. When the angles x and v are known, every thing else may be readily found.

If we suppose the beams AB, BD, to be of equal length, then $m = n$, and our two equations become

$$\frac{\tan x}{\tan v} = 3, \quad \sin (x - \gamma) = \sin (\gamma - v).$$

In this case, $x + v = 2\gamma$; then, from the equation

$$\frac{\tan x}{\tan v} = \frac{\sin x \cos v}{\cos x \sin v} = 3,$$

we get $\frac{\sin x \cos v - \cos x \sin v}{\sin x \cos v + \cos x \sin v} = \frac{\sin (x - v)}{\sin (x + v)} = \frac{1}{2}$;

and hence $\sin (x - v) = \frac{1}{2} \sin (x + v) = \frac{1}{2} \sin 2\gamma$;

and putting for v its value $2\gamma - x$,

$$\sin 2\,(x - \gamma) = \tfrac{1}{2} \sin 2\gamma.$$

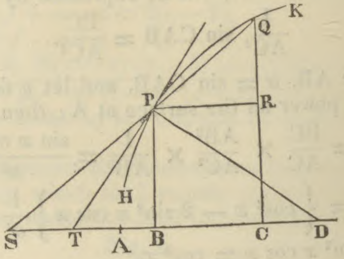
This determines the angle x, and $v = 2\gamma - x$.

The theory of equilibriums opens a wide field for the application of the calculus, as must be evident from the preceding solution; but our limits will not permit us to enter on it farther.

Determination of Tangents to Curves.

65. Let HPK be any curve referred to an axis AC; and let AB = x and PB = y be the co-ordinates of any point P in the curve; the point A being the origin of the abscisses. Let PT, a tangent to the curve at P, meet the axis in T; and let SPQ, any straight line drawn through P, meet the curve in Q and the axis in S. Draw QC perpendicular to the axis, and PR perpendicular to QC; and let PR = BC = h, and QC = y', the ordinate corresponding to the absciss $x + h$.

Fig. 6.



By similar triangles, QR : RP = PB : BS, that is,

$y' - y : h = y :$ BS.

Now, by Taylor's theorem (art. 31),

$$y' - y = \frac{dy}{dx} h + \frac{d^2y}{d^2x} h^2 + \&\text{c}.$$

hence, dividing the first antecedent and consequent by h,

$$\frac{dy}{dx}+\frac{d^2y}{dx^2}h+\text{ \&c.}:1=y:\text{BS}.$$

This proposition holds true whatever be the magnitude of h, the increment of x. But now let us suppose h to decrease continually; the point Q will approach to P, and the line QPS approaching to coincidence with PT, the point S will approach to T; and when h vanishes, Q will be at P, and S at T, and BS will have become BT; our proportion will now be

$$\frac{dy}{dx}:1=y:\text{BT}.$$

The line BT, between the ordinate PB and tangent PT, is called the *subtangent;* from this proportion it appears, that x and h being co-ordinates at any point in the curve,

$$\text{BT, the subtangent, }=y\div\frac{dy}{dx}=y\frac{dx}{dy};\ldots\ldots\ldots\ldots(1)$$

that is, the subtangent is equal to the ordinate divided by its differential co-efficient; or it is a third proportional to the differential of the ordinate, the differential of the abscissa and the ordinate. The subtangent being known, the position of the tangent is determined.

Let PD, a perpendicular to the tangent at P, and consequently to the curve, meet the axis in D; the line PD is called a *normal* to the curve; and BD, the segment of the axis between the ordinate and normal, is called the *subnormal.*

The triangles TBP, PBD are similar, therefore

$$\text{TB}:\text{BP}=\text{BP}:\text{BD},\text{ or }dx:dy=y:\text{BD},$$

$$\text{hence the } \textit{subnormal} \text{ BD}=y\frac{dy}{dx}\ldots\ldots\ldots(2).$$

Because the tangent of the angle $\text{PTB}=\frac{\text{PB}}{\text{TB}}$, and the tangent of the angle $\text{PDB}=\frac{\text{PB}}{\text{BD}}$; therefore,

$$\tan \textit{angle}\ \text{T}=\frac{dy}{dx},\text{ and }\tan\text{D}=\frac{dx}{dy}\ldots\ldots\ldots(3).$$

In the right-angled triangles TBP, PBD, we have $\text{PT}^2=\text{PB}^2+\text{BT}^2$, and $\text{PD}^2=\text{PB}^2+\text{BD}^2$; therefore,

$$\textit{tangent}\ \text{PT}=y\sqrt{1+\frac{dx^2}{dy^2}}\ \ldots\ldots\ldots\ldots\ldots\ (4)$$

$$\textit{normal}\ \text{PD}=y\sqrt{1+\frac{dy^2}{dx^2}}\ldots\ldots\ldots\ldots\ldots\ldots(5)$$

66. We shall now apply these general formulæ to some particular curves.

Ex. 1. Let the curve be the parabola, and supposing AC to be the axis, and A its vertex: by the nature of the curve, putting a for the parameter, $y^2=ax$,

$$\text{hence } 2ydy=adx;\ \frac{dx}{dy}=\frac{2y}{a},$$

$$\text{subtan. BT}=\frac{dx}{dy}y=\frac{2y^2}{a}=\frac{2ax}{a}=2x;$$

that is, the subtangent is double the absciss AB.

Again, for the subnormal, we have

$$\text{subnor. BD}=\frac{dy}{dx}y=\frac{adx}{2dx}=\frac{a}{2}.$$

Thus it appears that the subnormal is constant, and equal to half the parameter.

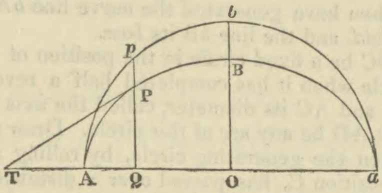
Ex. 2. Let the curve be an ellipse, of which OA half the greater axis $=a$, OB half the lesser axis $=b$; and supposing the origin of the co-ordinates to be at O the centre, let $\text{OQ}=x$, $\text{PQ}=y$. By the nature of the curve,

$$a^2:b^2=(a+x)(a-x):y^2\text{ (Conics)};$$

$$\text{hence } y^2=\frac{b^2}{a^2}(a^2-x^2),\text{ and } ydy=-\frac{b^2xdx}{a^2};$$

$$\text{and subtan. QT}=\frac{dx}{dy}y=-\frac{a^2y^2}{b^2x}=-\frac{a^2-x^2}{x}=-\left(\frac{a^2}{x}-x\right).$$

Fig. 7.



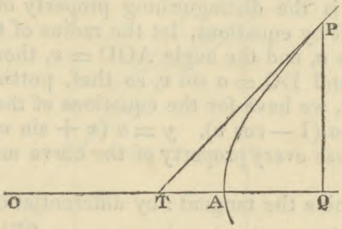
The general formula for the subtangent was found on the hypothesis that it was on the same side of the ordinate as the absciss; in this case they are supposed to be on opposite sides, and hence its value has the negative sign; leaving the direction of the subtangent in respect of the absciss out of consideration, we have

$$\text{QT}=\frac{a^2}{x}-x,\text{ and OT}=\frac{a^2}{x},$$

hence it appears that OQ : OA = OA : OT.

When the axes are equal, the ellipse becomes a circle, but the subtangent is independent of the ratio of the axes.

Fig. 8.



Ex. 3. Let the curve be the hyperbola, of which $a=\text{OA}$ the semitransverse axis, and $b=$ the semiconjugate; then, putting $\text{OQ}=x$, and $\text{PQ}=y$, we have (by Conics),

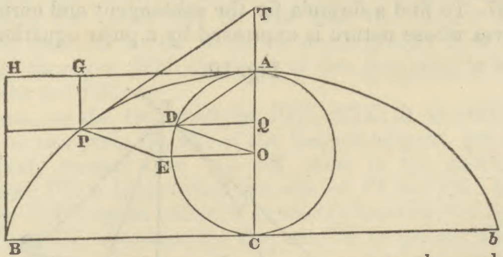
$$y^2=\frac{b^2}{a^2}(x^2-a^2),\quad ydy=\frac{b^2}{a^2}xdx;$$

$$\text{subtan. QT}=\frac{dx}{dy}y=\frac{a^2y^2}{b^2x}=\frac{x^2-a^2}{x}=x-\frac{a^2}{x};$$

$$\text{hence OT}=\text{OQ}-\text{QT}=\frac{a^2}{x}.$$

This shows that the tangent always passes between the centre and the vertex when x has a finite value; but when x becomes infinite, then $\text{OT}=0$, and the tangent becomes an asymptote to the hyperbola.

Fig. 9.



Ex. 4. We shall next draw a tangent to the cycloid; but first the nature of the curve must be expressed analytically. Conceive a circle to roll along a straight line, moving always in the same plane, just as the wheel of a carriage rolls along a straight road. By this motion any given point in the circumference of the circle will describe

Direct Method.

a continuous curve in that plane, which will meet the line along which it rolls at intervals equal to its circumference.

Let bB be the line along which a circle CDA rolls, beginning its motion from a point of contact b, and completing a revolution when it has come to B. The point of the circumference which was in contact with the line at b will then have generated the curve line bAB. This is the *cycloid*, and the line bB its *base*.

Let ADC be a fixed circle in the position of the *generating* circle when it has completed half a revolution, O its centre, and AC its diameter, called the axis of the cycloid. Let AD be any arc of this circle. Draw the radius OD. When the generating circle, by rolling along CB from the position C, has passed over a distance equal to the arc AD, the centre O will have generated a straight line OE parallel to CB, and equal to the same arc AD; moreover, the moveable radius, which was coincident with OA, will, by the rotation of the circle, have come into a position EP, parallel to OD, because the angular motion of the radius about the moving point E will always be proportional to the arc of the circle that has been applied to the base, that is, by hypothesis, to the arc AD; and since the lines OD, EP are equal and parallel, a straight line drawn from P through D, meeting AC in Q, will be parallel to EO, and therefore perpendicular to AC; and since PD = OE = arc AD, it follows that PQ, any ordinate to the axis AC, is equal to the sum of the arc AD and its sine DQ. This is the distinguishing property of a cycloid. To express it by equations, let the radius of the generating circle be a, and the angle AOD $= v$, then PD = arc AD $= av$, and DQ $= a \sin v$, so that, putting AQ $= x$, and PQ $= y$, we have for the equations of the curve

$$x = a\,(1 - \cos v), \quad y = a\,(v + \sin v);$$

and from these every property of the curve may be investigated.

To determine the tangent: by differentiation,

$$dx = a \sin v, \quad dy = adv\,(1 + \cos v), \quad \frac{dx}{dy} = \frac{\sin v}{1 + \cos v},$$

$$\text{subtan QT} = y\frac{dx}{dy} = \frac{(v + \sin v) \sin v}{1 + \cos v} = \frac{\text{PQ . QD}}{\text{CQ}};$$

hence CQ : DQ = PQ : QT.

But by the nature of the circle CQ : DQ = DQ : QA; therefore PQ : QT = DQ : QA; hence the triangles PQT, DQA are similar, and the tangent PT is parallel to the chord DA.

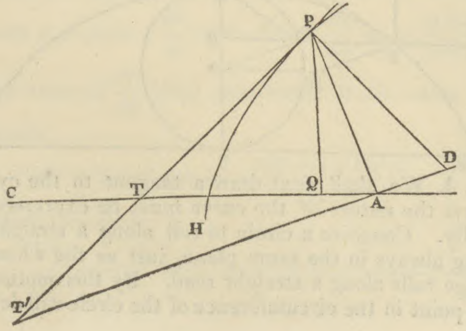
Ex. 5. In the logarithmic curve of which the equation is $y = a^x$, we have $dy = a^x\,.\,\text{l.}\,a\,.\,dx = y\,\text{l.}\,a\,.\,dx$; therefore

$$\frac{dx}{dy}y = \frac{1}{\text{l.}\,a} = \text{subtangent.}$$

Hence it appears that the subtangent is a line of a constant given length.

67. To find a formula for the subtangent and normal of curves whose nature is expressed by a polar equation.

Fig. 10.



Let HPK be such a curve, generated by the revolution of a variable radius AP about a given point A in AC, a line given in position. Through A draw AT′ perpendicular to AP; let a tangent to the curve at P meet this line in T′ and the axis in T; draw PQ perpendicular to the axis AC, and draw the normal PD, meeting T′A in D. Then AT′ is the subtangent and AD the subnormal. Let AQ $= x$, PQ $= y$, the revolving radius AP $= r$, the variable angle PAC $= v$, and the angle PTA $= t$. The lines x, y, r are now to be considered as functions of the angle v.

The angle T′PA being the supplement of the sum of PTA and PAT; that is, of $v + t$, we have (ALGEBRA, art. 236 and 242),

$$\tan \text{angle T'PA} = -\tan\,(v + t) = \frac{\tan v + \tan t}{\tan v \tan t - 1}.$$

$$\text{Now } \tan v = \frac{y}{x}, \text{ and } \tan t = \frac{\text{PQ}}{\text{TQ}} = -\frac{dy}{dx};$$

$$\text{therefore } \tan \text{T'PA} = \frac{\dfrac{y}{x} - \dfrac{dy}{dx}}{-\dfrac{ydy}{xdx} - 1} = \frac{xdy - ydx}{xdx + ydy}.$$

$$\text{Again, } \frac{xdy - ydx}{x^2} = d\left(\frac{y}{x}\right) = d\,(\tan v) = \frac{dv}{\cos^2 v},$$

$$\text{therefore } xdy - ydx = dv\frac{x^2}{\cos^2 v} = r^2dv;$$

$$\text{and } xdx + ydy = \tfrac{1}{2}d\,(x^2 + y^2) = \tfrac{1}{2}d\,(r^2) = rdr;$$

$$\text{therefore } \tan \text{T'PA} = \frac{r^2dv}{rdr} = \frac{rdv}{dr};$$

and since by trigonometry T′A = AP tan TPA, therefore

$$\text{subtangent T'A} = \frac{dv}{dr}r^2;$$

also, since T′A : AP = AP : AD; therefore

$$\text{subnormal AD} = \frac{dr}{dv}.$$

Ex. Let the curve PH be the spiral of Archimedes, the nature of which is defined by the equation $2\pi r = av$, where $\pi = 2$ right angles, and a is a given line, viz. the value of r when $v = 2\pi$. In this case

$$\text{subtangent} = \frac{dv}{dr}\,.\,r^2 = \frac{2\pi r^2}{a}.$$

68. In some curves the segment of the axis between the origin of the co-ordinates and the tangent increases with the variable x, and may exceed any given line. In others the tangent cuts the axis always at a finite distance from the origin; it is then an *asymptote* to the curve. If from the subtangent QT $= \frac{dx}{dy}y$ (fig. 8) the absciss AQ $= x$ be subtracted, the remainder $\frac{dx}{dy}y - x$ is the general expression for AT. Now if when x is infinite this expression is finite, we may conclude that the curve has asymptotes; but if it be infinite, the curve has no asymptotes.

In the conic hyperbola we found (ex. 3, art. 66) $\frac{dx}{dy}y = x - \frac{a^2}{x^2}$; therefore $\frac{dx}{dy}y - x = -\frac{a^2}{x^2}$; when x is infinite, the expression $-\frac{a^2}{x} = 0$, hence it follows that the hyperbola has an asymptote which passes through the centre.

In the parabola, ex. 1, we found $\frac{dx}{dy}y = \frac{2y^2}{ax}$, therefore

$\frac{dx}{dy}y - x = \frac{2y^2}{a} - x = 2x - x = x$. When x is infinite this quantity is also infinite, therefore the parabola has no asymptote.

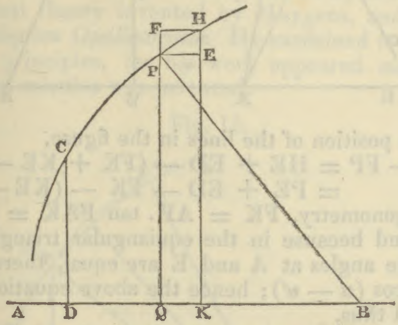
The method of drawing tangents to curves is an important branch of the theory of curve lines. It serves also to determine their greatest and least ordinates (which may also be found by the theory of *maxima* and *minima*), and many other circumstances relating to their figure.

Differential of the Area of a Curvilineal Space, and of the Arc of a Curve.

69. In curve lines it is convenient to consider x, one of the co-ordinates, as an independent variable quantity; and any area having an arc of the curve for a boundary, also the arc, and in general every other variable quantity connected with the curve, as functions of that variable. If the curve be expressed by a polar equation, the angle which the revolving radius makes with the variable may be taken as the independent variable, and the co-ordinates and other variable quantities related to the curve as functions of that angle.

We begin by investigating a formula for the area.

Fig. 11.



Let AB be the axis of any curve CP, A and C given points in the axis and curve, PQ, HK any two variable ordinates, and CD an ordinate given in position at the given point C; draw PE and HF perpendiculars to HK, PQ.

Put AQ $= x$, PQ $= y$, *curvilineal space* PQDC $= s$;
AK $= x'$, HK $= y'$, HKDC $= s'$;
then QK $= x' - x$, and PHKQ $= s' - s$.

The space PHKQ is greater than the rectangle PEKQ, but less than the rectangle FHKQ (supposing y to increase from the position PQ to HK), therefore,

$$s' - s > (x' - x)\,y,\quad s' - s < (x' - x)\,y';$$

$$\text{and } \frac{s' - s}{x' - x} > y,\quad \frac{s' - s}{x' - x} < y'.$$

Hence, since when HK approaches to coincidence with PQ, y' approaches to equality with y, we have

$$\frac{ds}{dx} = \text{lim.}\ \frac{s' - s}{x' - x} = y,$$

$$\text{and } ds = ydx \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(1).$$

Thus it appears that *The differential of a curvilineal area is the product of the ordinate and the differential of the absciss.*

In the formula just found, the ordinates have been supposed perpendicular to the axis. If they be oblique, let α be the angle of inclination; then $s' - s$ will be greater than $(x' - x)\,y \,.\, \sin\alpha$, but less than $(x' - x)\,y' \,.\, \sin\alpha$; and hence, reasoning as before, we find

$$ds = \sin\alpha \,.\, ydx \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(2).$$

70. To find a formula applicable when the nature of the curve is expressed by a polar equation, let B be the pole, and PB the variable radius.

Put PB $= r$, the angle PBQ $= v$, and the curvilineal space PCDB $= s$; also let BQ $= x$, PQ $= y$, then

$$ds = d\,(\text{space CDQP}) + d\,(\text{triangle PQB}).$$

Now d (space CDQP) $= -\,ydx$, which is negative, because x decreases when the space increases; and d (triangle PQB) $= d\,(\frac{1}{2}\,xy) = \frac{1}{2}\,ydx + \frac{1}{2}\,xdy$; therefore,

$$ds = -\,ydx + \tfrac{1}{2}\,ydx + \tfrac{1}{2}\,xdy = \tfrac{1}{2}\,(xdy - \tfrac{1}{2}\,ydx)$$
$$= x^2 d\left(\frac{y}{x}\right) \text{ (art. 12).}$$

But in the right-angled triangle PBQ,

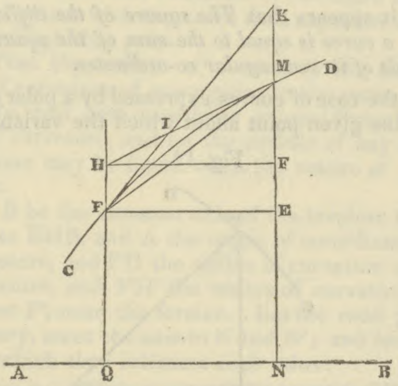
$$\text{BQ} = x = r\cos v,\quad \frac{y}{x} = \tan v,\quad d\left(\frac{y}{x}\right) = \frac{dv}{\cos^2 v} \text{ (art. 22)};$$

$$\text{hence } ds = \tfrac{1}{2}\,r^2 dv \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(3).$$

In this case *The differential of the area is half the product of the square of the revolving radius, and the differential of the angle which it makes with the axis.*

71. We have already found (art. 23) various expressions for the differential of the arc of one particular curve, viz. the circle. We shall now investigate general expressions for the differential of the arc of any curve. For this purpose it will be convenient to establish the following geometrical proposition.

Fig. 12.



Let CPMD be a curve, that between the points P and M continually approaches to or continually recedes from an axis AB. Let PQ, MN be ordinates to the axis at the extremities of the arc PM, and PK, MH tangents to the curve at the points P, M, meeting the ordinates in K and H: The length of the arc is always of an intermediate magnitude between the lengths of the tangents PK, MH.

Draw the chord PM, and let I be the intersection of the tangents. It is easy to see that PK, one of the tangents, meets the parallel ordinates in an angle K more acute than M, the angle made by the chord PM and ordinate MN; and the other in an angle H less acute; therefore the chord will be less than the former and greater than the latter. Now the arc is greater than the chord; therefore MH, the least of the tangents, is less than the arc PM.

Again, in the two triangles PIH, MIK, it is evident that the two parts PI, IK, of the longest tangent, are respectively greater than HI, IM, those of the shorter; therefore PK is longer than the sum of PI and IM; but the arc PM is by an axiom of geometry less than the sum of PI and IN, therefore the tangent PK is greater than the arc PM.

72. Let A be a given point in the axis, and C in the curve; draw PE, HF parallel to AB; put AQ $= x$, AN $= x'$, PQ $= y$, CP $= z$, CM $= z'$; then PE $= x' - x$, and arc PM $= z' - z$. Because PM $= z' - z$ is less than PK, but greater than MH, therefore

Direct Method.

$$\frac{z'-z}{x'-x} < \frac{\mathrm{PK}}{\mathrm{PE}}, \text{ and } \frac{z'-z}{x'-x} > \frac{\mathrm{HM}}{\mathrm{HF}}.$$

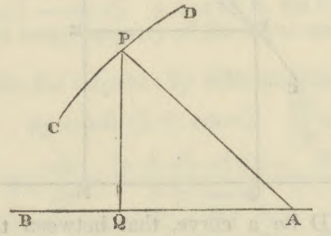
Now $\frac{\mathrm{PK}}{\mathrm{PE}}$ and $\frac{\mathrm{HM}}{\mathrm{HF}}$ are the secants of the angles KPE and MHF; therefore the ratio $\frac{z'-z}{x'-x}$ is expressed by a quantity less than the secant of one of these angles, and greater than the secant of the other angle. Suppose now $z'-z$ and $x'-x$, the terms of the ratio, to be continually diminished; the angles at H and P will approach to equality, and at last become equal, therefore the limit of the ratio, viz. $\frac{dz}{dx}$, is equal to the secant of the angle KPE; but it was shown (art. 65) that the tangent of the angle which a line touching a curve makes with the axis, or any line parallel to the axis, is equal to $\frac{dy}{dx}$, and consequently its secant to $\sqrt{1+\frac{dy^2}{dx^2}}$; therefore

$$\frac{dz}{dx}=\sqrt{1+\frac{dy^2}{dx^2}} \text{ and } dz=\sqrt{dx^2+dy^2}\ldots\ldots\ldots\ldots(1)$$

Hence it appears that *The square of the differential of the arc of a curve is equal to the sum of the squares of the differentials of its rectangular co-ordinates.*

73. In the case of curves expressed by a polar equation, let A be the given point about which the variable radius AP turns; put v for the variable angle which the line AP $= r$ makes with AB, a line given in position; let the rectangular co-ordinates be AQ $= x$, PQ $= y$; then

Fig. 13.



$$x = r\cos v,\ y = r\sin v;$$

$$dx = -r\sin v\,dv + \cos v\,dr = -ydv + \frac{x}{r}dr;$$

$$dy = r\cos v\,dv + \sin v\,dr = xdv + \frac{y}{r}dr;$$

$$dx^2 = y^2dv^2 + \frac{x^2}{r^2}dr^2 - \frac{2xy}{r}dvdr;$$

$$dy^2 = x^2dv^2 + \frac{y^2}{r^2}dr^2 + \frac{2xy}{r}dvdr;$$

$$\text{therefore, } dx^2+dy^2=(x^2+y^2)\left(dv^2+\frac{dr^2}{r^2}\right).$$

$$\text{But } dx^2+dy^2=dz^2, \text{ and } x^2+y^2=r^2;$$
$$\text{therefore, } dz^2=r^2dv^2+dr^2,$$
$$\text{and } dz=\sqrt{r^2dv^2+dr^2}\ldots\ldots\ldots\ldots\ldots\ldots(2)$$

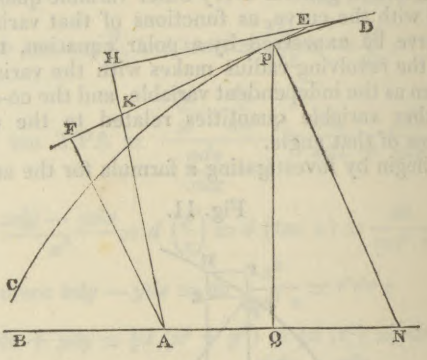
This formula gives the differential of an arc of a curve in terms of the differential of the variable *radius vector*, and the angle which it makes with the axis.

74. We shall now give a method of defining a curve by a polar equation, which leads to a simple and elegant expression for the differential of an arc of the curve.

Let CPD be any curve, and A a given point in AB, a line given by position; draw a tangent PF at any point P in the curve, and a perpendicular AF from the given point A on the tangent; if now we know the relation between the perpendicular AF, and the angle FAB, which it makes with the line AB, the length of the perpendicular corresponding to any given value of the angle can be found; thus the position of the tangent will be known; the calculus gives a general formula for PF, the segment of the tangent between the point of contact and its intersection with the perpendicular; thus the point of contact P is known, and in this way may any number of points in the curve be determined.

75. Let D be another point in the curve, DH a tangent, and AH a perpendicular on the tangent, and let us put angle FAB $= u$, perp. AF $= p$, tan PF $= t$, arc CP $= z$;
HAB $= u'$, AH $= p'$, DH $= t'$, CD $= z'$

Fig. 14.



From the position of the lines in the figure,

$$\mathrm{HD}-\mathrm{FP}=\mathrm{HE}+\mathrm{ED}-(\mathrm{FK}+\mathrm{KE}-\mathrm{EP})$$
$$=\mathrm{PE}+\mathrm{ED}-\mathrm{FK}-(\mathrm{KE}-\mathrm{HE}).$$

By trigonometry, FK $=$ AF . tan FAK $= p\tan(u'-u)$; and because in the equiangular triangles AFK, EHK, the angles at A and E are equal, therefore HE $=$ KE . $\cos(u-u')$; hence the above equation may be expressed thus,

$$t-t'=\mathrm{PE}+\mathrm{ED}-p.\tan(u'-u)-\{1-\cos(u'-u)\}\mathrm{KE};$$

and dividing by $u'-u$,

$$\frac{t'-t}{u'-u}=\frac{\mathrm{PE}+\mathrm{ED}}{u'-u}-p.\frac{\tan(u'-u)}{u'-u}-\frac{1-\cos(u'-u)}{u'-u}\mathrm{KE}.$$

Suppose now the point D to approach to coincidence with P, we have these limits to the ratios:

$$\lim.\frac{t'-t}{u'-u}=\frac{dt}{du}; \qquad \lim.\frac{\mathrm{PE}+\mathrm{ED}}{u'-u}=\frac{dz}{du};$$

$$\lim.\frac{\tan(u'-u)}{u'-u}=1; \qquad \lim.\frac{1-\cos(u'-u)}{u'-u}$$

$$=\lim.\frac{2\sin^2\frac{1}{2}(u'-u)}{u'-u}=0;$$

hence, on the whole,

$$\frac{dt}{du}=\frac{dz}{du}-p, \text{ and } dz=dt+pdu,$$
$$\text{or } d(z-t)=pdu.$$

In the figure from which the formula has been investigated, the arc and tangent lie in the same direction from the point of contact. If they had proceeded in contrary directions, the formula would have been $d(z+t)=pdu$, so that, in general,

$$d(z\mp t)=pdu\ldots\ldots\ldots\ldots\ldots(3)$$

The differential of the arc may be expressed independently of t; for

$$\mathrm{AH}-\mathrm{AF}=\mathrm{KH}+\mathrm{AK}-\mathrm{AF};$$

Now KH $=$ HE . tan HEK $=$ HE $\tan(u'-u)$, and AF $=$ AK $\cos(u'-u)$; therefore, dividing by $u'-u$, we have

Direct Method.

$$\frac{p' - p}{u' - u} = \mathrm{HE}\,\frac{\tan(u' - u)}{u' - u} + \frac{1 - \cos(u' - u)}{u' - u}\,\mathrm{AK}:$$

and, passing to the limits, observing that lim. HE $= t$,

$$\lim.\frac{\tan(u' - u)}{u' - u} = 1, \text{ and } \lim.\frac{1 - \cos(u' - u)}{u' - u} = 0,$$

we find $\frac{dp}{du} = t$; if the tangent and arc lie in contrary directions, then $-\frac{dp}{du} = t$, so that, including both cases in one formula, $t = \pm\frac{dp}{du}$.

The sign $+$ is to be taken when the arc and tangent lie in the same direction, but the sign $-$ when they have contrary directions; and because $dt = \pm\frac{d^2p}{du}$, therefore in every curve

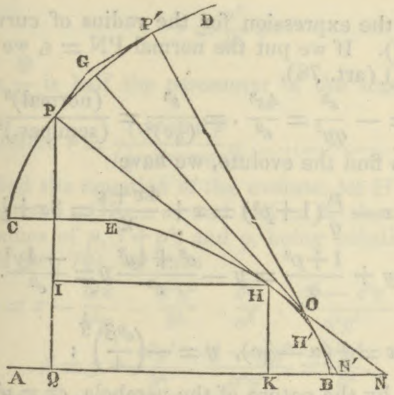
$$dz = pdu + \frac{d^2p}{du^2}\,du = \left(p + \frac{d^2p}{du^2}\right)du \ldots\ldots\ldots\ldots (4)$$

This is the formula which was to be found.

Generation of Curves by Evolution: Radius of Curvature: Evolutes.

76. The method of generating curves by evolution is a geometrical theory invented by Huygens, and given in his *Horologium Oscillatorium.* He explained it upon geometrical principles, for his work appeared many years before the calculus was invented.

Fig. 15.



Let BHE be a model of a plane curve made of a solid material, having some thickness, and let one end of a thread HEC be fastened at a point B on the edge of the model, and applied along its convexity, so as to coincide with it entirely between B and E, the remaining portion EC of the thread forming a straight line touching the curve at E. Suppose now the thread to be gradually unlapped from the curve BE, keeping it always tight; the end C will now describe another curve CPD.

All curves, in which the curvature is neither infinitely great nor infinitely small, may be generated in this way by the evolution of a thread from another curve.

77. The curve EHB, by means of which the curve CPD is generated, is called its EVOLUTE; and the curve CPD thus generated by evolution, is called the INVOLUTE of the other curve.

From the way in which the involute is generated from its evolute, we may infer,

(1.) That PH, the part of the thread disengaged from the arc EH, is a tangent to the evolute at H.

(2.) That the line PH is perpendicular to a tangent to the curve CPD at P, and that at the same time it describes an element of the curve, and an element of a circle whose momentary centre is H and radius HP.

(3.) That to a certain extent the part of the involute adjoining to P, and towards C, is *more* incurvated than a circle whose radius is PH; because, supposing P to proceed towards C, the variable radius PH is gradually becoming shorter. On the other hand, a portion of the curve from P towards D is *less* incurvated than a circle whose radius is CP, because the generating radius is continually becoming longer.

(4.) That since the curvature of the involute on one side of P, and adjoining to it, is less than that of a circle whose radius is PH, and the curvature on the other side of P is greater, it follows that at the point P the curvature of the involute is exactly the same as that of a circle described with the radius HP. The point H is therefore called the *centre of curvature* of the curve CPD in the point P; and PH, its *radius of curvature* at that point; and a circle described with the line PH is the *circle of equal curvature* with the curve at the point P. From the close union of the circle and curve they have been said to *osculate.* It must, however, be kept in mind that the two curves have no common segment; they meet in a geometrical point at P, and separate on both sides of it. We may also infer that the circle of curvature has a more intimate contact with the curve than any other circle that passes through that point.

(5.) That the evolute of a curve is the *locus* of the centre of curvature of every point in the curve.

78. We shall now investigate general formulæ for the radius of curvature, and for the evolute of any curve, by which these may be found when the nature of the curve is known.

Let AB be the common axis of the involute CPD, and its evolute EHB, and A the origin of co-ordinates; let H be the centre, and PH the radius of curvature at P; and H′ the centre, and P′H′ the radius of curvature of another point P′, near the former. Let the radii produced, if necessary, meet the axis in N and N′; and let O be the point in which they intersect each other.

Put AQ $= x$, PQ $= y$, arc CP $= z$, arc CP′ $= z'$, angle PNA $= v$, angle P′N′A $= v'$, rad. of curv. PH $= r$.

By trigonometry, PG = OG . sin POG; P′G = OG . sin P′OG; therefore, $\mathrm{OG} = \frac{\mathrm{PG} + \mathrm{P'G}}{\sin \mathrm{POG} + \sin \mathrm{P'OG}}$.

Suppose now the points P′, P to approach continually towards coincidence, the line GO will manifestly have for its limit PH, the radius of curvature at P. The limit of the sum of the tangents PG, P′G will be the arc PP′ $= z' - z$. The limit of the sines of the angles POG, P′OG will be the arcs which measure the angles, and that of the sum of the sines will be the measure of the angle POP = NON $= v' - v$. Hence it appears that $r =$ limit of $\frac{z' - z}{v' - v}$, and therefore, that

$$r = \frac{dz}{dv} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (1)$$

This is our first general expression for the radius of curvature. Put $\frac{dy}{dx} = p$, $\frac{d^2y}{dx^2} = \frac{dp}{dx} = q$.

Because (art. 72) $dz = \sqrt{dx^2 + dy^2} = dx\sqrt{1 + \frac{dy^2}{dx^2}}$, therefore $dz = dx\sqrt{1 + p^2}$.

When treating of tangents to curves, we found (art. 65) that $\tan v = \frac{dx}{dy}$, therefore, $\tan v = \frac{1}{p}$, $\sec v = \frac{\sqrt{1 + p^2}}{p}$,

$$\text{and } d(\tan v) = dv \sec^2 v = -\frac{dp}{p^2};$$

$$\text{hence, } \frac{1+p^2}{p^2}dv = -\frac{qdx}{p^2}, \text{ and } dv = -\frac{qdx}{1+p^2}.$$

If now the values of dz and dv be substituted in our first formula for the radius of curvature, there is obtained

$$r = -\frac{1}{q}(1+p^2)^{\frac{3}{2}} = -\frac{(dx^2+dy^2)^{\frac{3}{2}}}{dxdy^2} \dots\dots\dots\dots (2)$$

This is a second general formula for the radius of curvature.

Let s denote the normal PN. In the right-angled triangle PQN, by trigonometry, $\sin \text{N} = \frac{\text{PQ}}{\text{PN}}$, that is, $\sin v = \frac{y}{s}$; but since

$$\tan v = \frac{dx}{dy} = \frac{1}{p}, \text{ therefore } \frac{y}{s} = \sin v = \frac{1}{\sqrt{1+p^2}},$$

$$\text{and } \sqrt{1+p^2} = \frac{s}{y}, \text{ and } (1+p^2)^{\frac{3}{2}} = \frac{s^3}{y^3}.$$

Referring now to our second formula, we have

$$r = -\frac{s^3}{qy^3} = -\frac{s^3}{y^3} \cdot \frac{dx^2}{dy^2} \dots\dots\dots\dots\dots\dots (3)$$

This is a third formula for the radius of curvature.

If we suppose the nature of the curve (see fig. 14, art. 74) expressed by an equation between AF $= p$, a perpendicular from a given point in the axis on a tangent PF, and FAP $= v$, the angle which that perpendicular makes with the axis, and therefore also equal to the angle which the normal PN makes with the axis; then, since $dz = \left(p + \frac{d^2p}{dv^2}\right)dv$; from formula (1) we get also

$$r = p + \frac{d^2p}{dv^2} \dots\dots\dots\dots\dots\dots (4)$$

This is a fourth formula for the radius of curvature.

79. To determine the nature of the evolute EHB, from any point H in the curve draw HK perpendicular to AB, and HI perpendicular to PQ; and assuming A, the origin of the co-ordinates of the involute also as the origin of those of the evolute, let AK $= \alpha$, HK $= \beta$; in the triangle PHI, HI $=$ PH . cos H $= r \cos v$, and PI $= r \sin v$, therefore

$$\alpha = x + r\cos v, \qquad \beta = y - r \sin v.$$

We have found that $\tan v = \frac{1}{p}$, and therefore

$$\cos v = \frac{p}{\sqrt{1+p^2}}, \qquad \sin v = \frac{1}{\sqrt{1+p^2}};$$

hence, combining these with the expressions for r, we have

$$\alpha = x - \frac{p}{q}(1+p^2), \qquad \beta = y + \frac{1}{q}(1+p^2);$$

or, substituting for p and q the quantities they denote,

$$\alpha = x - \frac{dy}{dx} \cdot \frac{dx^2+dy^2}{d^2y}, \qquad \beta = y + \frac{dx^2+dy^2}{d^2y}.$$

In these formulæ, and in the second and third for the radius of curvature, x is regarded as the independent variable, and y as a function of x.

80. From the way in which a curve may be generated by an evolute, we have a method of finding any number of curves which may be rectified, that is, whose length may be assigned in algebraic terms; for PH, the radius of the curvature, is the sum of the straight line CE, and the arc EH of the evolute. Now we can form innumerable curves whose radius of curvature will be known, therefore, corresponding to every curve whose radius of curvature can be found and expressed in algebraic terms, there is a curve which can be exactly rectified.

81. We shall now give examples of the application of the formulæ.

Ex. 1. Let the curve be a parabola, of which AC is the axis: let c denote the parameter, and let AQ $= x$, and PQ $= y$, be the co-ordinates of P, any point in the curve. Let CH be the evolute, and let AK $= \alpha$, HK $= \beta$, be the co-ordinates of H, the centre of curvature at P, the radius of curvature being PH $= r$.

By the nature of the curve, $y^2 = cx$, therefore,

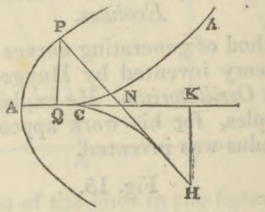
$$\frac{dy}{dx} = p = \frac{c}{2y}; \; 1+p^2 = \frac{c^2+4y^2}{4y^2} = \frac{c+4x}{4x};$$

$$\frac{d^2y}{dx^2} = \frac{dp}{dx} = q = -\frac{c}{2}\frac{dy}{dx} \cdot \frac{1}{y^2} = -\frac{c^2}{4y^3};$$

$$r = -\frac{(1+p^2)^{\frac{3}{2}}}{q} = \frac{(c^2+4y^2)^{\frac{3}{2}}}{2c^2} = \frac{(c^2+4cx)^{\frac{3}{2}}}{2c^2}$$

$$= \tfrac{1}{2}\sqrt{\frac{(c+4x)^3}{c}}.$$

Fig. 16.



This is the expression for the radius of curvature by formula (2). If we put the normal PN $= s$, we have, by formula (3) (art. 78),

$$r = -\frac{s^3}{qy^3} = \frac{4s^3}{c^2} \cdot = \frac{s^3}{(\frac{1}{2}c)^2} = \frac{(\text{normal})^3}{(\text{semipar.})^2}.$$

Next, to find the evolute, we have

$$\alpha = x - \frac{p}{q}(1+p^2) = x + \frac{4x+c}{2} = 3x + \tfrac{1}{2}c;$$

$$\beta = y + \frac{1+p^2}{q} = y - \frac{c^2+4y^2}{c^2}y = \frac{-4y^3}{c^2}.$$

$$\text{Hence } x = \tfrac{1}{3}(\alpha - \tfrac{1}{2}c), \;\; y = -\left(\frac{c^2\beta}{4}\right)^{\frac{1}{3}};$$

and since, by the nature of the parabola, $cx = y^2$; therefore the equation of the evolute is

$$\beta^2 = \frac{16}{27c^2}\left(\alpha - \frac{c}{2}\right)^3;$$

Take AC $= \frac{1}{2}c$, then C is a given point; and CK $= \alpha - \frac{1}{2}c$. Put CK $= x'$; HK $= \beta = -y'$, and the equation of the involute becomes

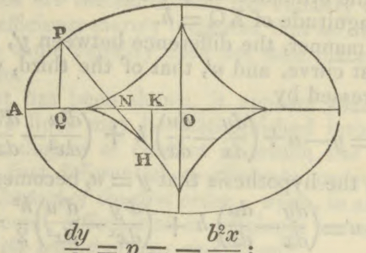
$$y'^2 = \frac{16}{27c}x'^3.$$

Hence it appears that the evolute is the semicubical parabola. This is the first curve that was rectified by the infinitesimal calculus.

Ex. 2. Let the curve be an ellipse, of which OA $= a$ is the semitransverse axis, and OB $= b$ the semiconjugate. Let $e = \sqrt{a^2 - b^2}$ be the eccentricity, and, assuming the centre as the origin of co-ordinates, let OQ $= x$, PQ $= y$, HP, the radius of curvature at P, $= r$.

The equation of the curve is $\frac{x^2}{a^2} + \frac{y^2}{b^2} = 1$; or $b^2x^2 + a^2y^2 = a^2b^2$: Hence

Fig. 17.



$$\frac{dy}{dx} = p = -\frac{b^2x}{a^2y};$$

$$1+p^2 = \frac{b^2}{a^2}\cdot\frac{a^4-(a^2-b^2)\,x^2}{a^2y^2} = \frac{b^2}{a^2}\cdot\frac{a^4-e^2x^2}{a^2y^2}$$

$$= \frac{b^4+(a^2-b^2)\,y^2}{a^2y^2} = \frac{b^4-e^2y^2}{a^2y^2}.$$

$$\frac{d^2y}{dx^2} = \frac{dp}{dx} = q = -\frac{b^2}{a^2y} + \frac{b^2x}{a^2y^2}\cdot\frac{dy}{dx} = -\frac{b^4}{a^2y^3};$$

$$\frac{(1+p^2)^{\frac{3}{2}}}{q} = \frac{-1}{a^4b}(a^4-e^2x^2)^{\frac{3}{2}} = \frac{-1}{ab^4}(b^4-e^2y^2)^{\frac{3}{2}}.$$

Hence the radius of curvature

$$r = \frac{1}{a^4b}(a^4-e^2x^2)^{\frac{3}{2}} = \frac{1}{ab^4}(b^4-e^2y^2)^{\frac{3}{2}}$$

$$= \frac{1}{a^4b^4}(a^4y^2+b^4x^2)^{\frac{3}{2}}.$$

The formula $r = -\frac{s^3}{y^3q}$ (where $s =$ the normal PN) gives this other value,

$$r = \frac{a^2}{b^4}s^3.$$

Now $\frac{b^2}{a}$ is half the parameter of the transverse axis;

therefore $r = \frac{(\text{normal})^3}{(\frac{1}{2}\text{ paramer})^2}$ ....(2)

To find the equation of the evolute, let H be any point in the curve; $OK = \alpha$, and $HK = \beta$, the co-ordinates. The values of p, $1+p^2$, and q, being substituted in the formula (art. 79), we have

$$\alpha = x - \frac{b^2x}{a^2y}\cdot\frac{a^2y^3}{b^4}\cdot\frac{b^2}{a^2}\cdot\frac{a^4-e^2x}{a^2y^2} = \frac{e^2x^3}{a^4}:$$

$$\beta = y - \frac{a^2y^3}{b^4}\cdot\frac{b^4-e^2y^2}{a^2y^2} = \frac{e^2y^3}{b^4}.$$

Let us exchange α and β for x' and y', and we have

$$\frac{x^2}{a^2} = \left(\frac{ax'}{e^2}\right)^{\frac{2}{3}};\quad \frac{y^2}{b^2} = \left(\frac{by'}{e^2}\right)^{\frac{2}{3}}.$$

Observing now that in the ellipse $\frac{x^2}{a^2} + \frac{y^2}{b^2} = 1$, we have for the equation of the evolute

$$\left(\frac{ax'}{e^2}\right)^{\frac{2}{3}} + \left(\frac{by'}{e^2}\right)^{\frac{2}{3}} = 1;\ \text{or}\ (ax')^{\frac{2}{3}} + (by')^{\frac{2}{3}} = (a^2-b^2)^{\frac{2}{3}}.$$

The form of this equation is remarkable from its analogy to that of the ellipse itself. The curve has the form shown in figure 17.

Ex. 3. Let the curve be the cycloid; of which let AA′ be the base, BC the axis, BDC a circle whose diameter is BC. From P any point in the curve, draw PDE perpendicular to the axis, meeting the circle in D; draw PQ perpendicular to the base, and let PH be the radius of curvature.

Since all cycloids are similar figures, we may make the radius of the generating circle = 1; let CQ = PE = x, PQ = CE = y, the arc BD = v.

By the nature of the cycloid (art. 66, ex. 4),

$$x = v + \sin v,\quad y = 1 - \cos v,$$

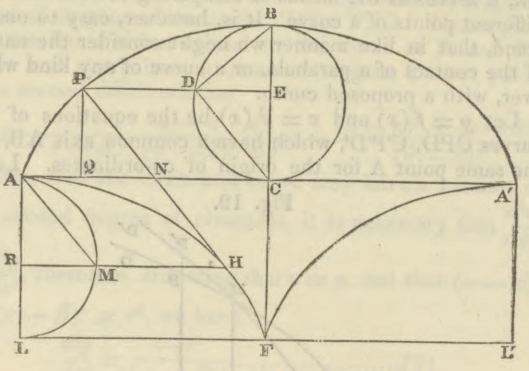
therefore $dx = dv\,(1+\cos v)$, $dy = dv \sin v$,

$$\frac{dy}{dx} = p = \frac{\sin v}{1+\cos v};\ 1+p^2 = \frac{2}{1+\cos v},\ dp = \frac{dv}{1+\cos v};$$

$$\frac{d^2y}{dx^2} = \frac{dp}{dx} = q = \frac{1}{(1+\cos v)^2},$$

Hence r, the rad. of cur. $= -\frac{(1+p^2)^{\frac{3}{2}}}{q} = \sqrt{8\,(1+\cos v)}.$

Fig. 18.



Draw the chord CD, and because

$1 + \cos v = 2\cos^2 \frac{1}{2}v$ (ALGEBRA, 249) $= 2\sin^2 \frac{1}{2}$ arc CD
$= \frac{1}{2}$ chord² CD.

Therefore, PH = r = 2 chord CD.

It was shown (art. 66) that a tangent at P is parallel to BD, the chord of the supplement of CD; therefore PH, which is perpendicular to the tangent, is parallel to the chord CD; it is therefore determined in position and magnitude for any given point in the curve.

The evolute AHF may be found by the general formula (art. 79), or otherwise from the expression for PH, the radius of curvature, thus:

Draw AL perpendicular to AC, and equal to BC, but on the opposite side of AC; describe the semicircle AML, and draw HMR perpendicular to AL, cutting the semicircle in M; let PH meet AC in N.

Because CA = semicircle CDB, and CN = DP = arc BD, therefore AN = arc CD. But because PH = 2CD = 2PN; and therefore PN = NH; the parallels PE, HR are equally distant from CA; and hence CE = RA, and arc CD = arc AM and chord CD = chord AM, also angle DCA = angle CAM. Now CD = PN = NH: therefore AM = NH; but AM is parallel to NH; therefore MH = AN = arc CD = arc AM; and HR = arc AM + sin MR; thus it appears that H is a point in a semicycloid having the same base as the cycloid ABA′. Indeed LAF is just the semicycloidal space CBA′ transferred to the position AHF, the point B being placed at A, and A′ at F. If the other semicycloidal space AB be transferred to the position FA′L′, the arc APB in the position FA′ will form another branch of the evolute, exactly similar to FA, but turned the contrary way.

From what has been found it appears, that if the semicycloids FLA, FL′A′ were placed in a vertical plane, with the point F uppermost, and the semi-bases FL, FL′ in a horizontal line; and if a weight were suspended from F by a thread equal in length to FB, and made to vibrate in that plane, like a pendulum; the weight would manifestly vibrate in an arc of a cycloid. This elegant property of the curve was discovered by Huygens, who also found that the vibrations would be isochronal, that is, performed in equal times. This is an important proposition in dynamics.

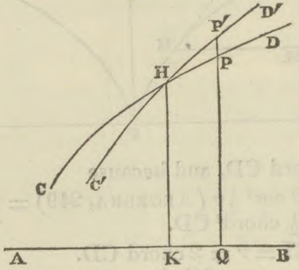
Contact of Curves.

82. The ancient geometers paid particular attention to the contact of straight lines, with the few curve lines which they considered. Apollonius even touched on the contact of circles and the conic sections; for he treated of the shortest line that can be drawn from a given point in the axis to the curve. It is only, however, since the invention of the differential calculus that this branch of geometry has been carried to any considerable extent.

83. The curvature of a circle being the same throughout, it serves as the means of comparing the curvature in different points of a curve. It is, however, easy to understand, that in like manner we might consider the nature of the contact of a parabola, or a curve of any kind whatever, with a proposed curve.

Let $y=f(x)$ and $v=\text{F}(x)$ be the equations of two curves CPD, C′P′D′, which have a common axis AB, and the same point A for the origin of co-ordinates. Let x be a common absciss, and y the corresponding ordinate of any point in the curve CD; also v, the like ordinate in the curve C′D′. Suppose now that when x becomes $x+h$, y becomes y', and v becomes v'; by Taylor's theorem,

Fig. 19.



$$y'=y+\frac{dy}{dx}h+\frac{d^2y}{dx^2}\,\frac{h^2}{1\,.\,2}+\&c.$$

$$v'=v+\frac{dv}{dx}h+\frac{d^2v}{dx^2}\,\frac{h^2}{1.2}+\&c.$$

Suppose now the curves to have a common point H, at which $y=v$; then, *If the curves be such that* $\frac{\text{dy}}{\text{dx}}=\frac{\text{dv}}{\text{dx}}$, *their contact at* P *will be of such a nature, that no third curve can pass between them at that point, unless it has a like property.*

Let HK $=y=v$, KQ $=h$, PQ $=y'$, P′Q $=v'$. Also, let $u=$ HK be the ordinate of a third curve that passes through H, and u' its value, corresponding to AQ $=x+h$, then

$$u'=u+\frac{du}{dx}h+\frac{d^2u}{dx^2}\,\frac{h^2}{1\,.\,2}+\&c.$$

We are to prove it to be impossible for the third curve, in leaving the point H, to pass between the arcs HP and HP′, unless $\frac{du}{dx}=\frac{dy}{dx}=\frac{dv}{dx}$. For suppose it possible, then, because in general

$$\text{PP}'=y'-v'=y-v+\left(\frac{dy}{dx}-\frac{dv}{dx}\right)h+\left(\frac{d^2y}{dx^2}-\frac{d^2v}{dx^2}\right)\frac{h^2}{2}+\&c.$$

and, because at the point H, $y=v$; and, in this particular case, $\frac{dy}{dx}=\frac{dv}{dx}$, we have

$$y'-v'=\left(\frac{d^2y}{dx^2}-\frac{d^2v}{dx^2}\right)\frac{h^2}{2}+\left(\frac{d^3y}{dx^3}-\frac{d^3v}{dx^3}\right)\frac{h^3}{6}+\&c.$$

This is the general expression for P′P′, the difference between the ordinates of the curves CD, C′D′, whatever be the magnitude of KQ $=h$.

In like manner, the difference between y', the ordinate of the first curve, and u', that of the third, will be generally expressed by

$$y'-u'=y-u+\left(\frac{dy}{dx}-\frac{du}{dx}\right)h+\left(\frac{d^2u}{dx^2}-\frac{d^2u}{dx^2}\right)\frac{h^2}{2}+\&c.$$

which, on the hypothesis that $y=u$, becomes

$$y'-u'=\left(\frac{dy}{dx}-\frac{du}{dx}\right)h+\left(\frac{d^2y}{dx^2}-\frac{d^2u}{dx^2}\right)\frac{h^2}{2}+\&c.$$

Now, if it were possible that the third curve, in leaving the common point H, could pass between the other two, we should, to a certain extent from the point H, have $y'-v'$ greater than $y'-u'$, that is, after dividing the expressions for $y'-v'$ and $y'-u'$ by h,

$$\left(\frac{d^2y}{dx^2}-\frac{d^2v}{dx^2}\right)\frac{h}{2}+\left(\frac{d^3y}{dx^3}-\frac{d^3v}{dx^3}\right)\frac{h^2}{6}+\&c.$$
$$>\frac{dy}{dx}-\frac{du}{dx}+\left(\frac{d^2y}{dx^2}-\frac{d^2u}{dx^2}\right)h+\&c.$$

And this equation ought to hold true, however small the line KQ $=h$ be taken. But h may be taken so small, that all the terms in the expression for $y'-v'$ shall be less than any assignable quantity, while those of $y'-u'$ continually approach to $\frac{dy}{dx}-\frac{du}{dx}$ as a limit, which by hypothesis is not equal to zero. Now these two conclusions are incompatible with each other; therefore it is impossible that the third curve can pass through the point P between the other two, when $\frac{dy}{dx}$ is not equal to $\frac{du}{dx}$.

If, however, $\frac{dy}{dx}=\frac{du}{dx}$, then the third curve may pass between the other two; for it will only be necessary that

$$\frac{d^2y}{dx^2}-\frac{d^2v}{dx^2}>\frac{d^2y}{dx^2}-\frac{d^2u}{dx^2},\ \text{that is,}\ \frac{d^2u}{dx^2}>\frac{d^2v}{dx^2},$$

which is evidently possible.

84. Again, if there be two curves whose equations are $y=f(x)$, $v=\text{F}(x)$, and which have a common ordinate $y=v$, and if they be such, that

$$\frac{dy}{dx}=\frac{dv}{dx},\quad \frac{d^2y}{dx^2}=\frac{d^2v}{dx^2};$$

then no third curve of which the equation is $u=\varphi(x)$, and which has a common ordinate with the other two, can pass between them, unless at the same time

$$\frac{dy}{dx}=\frac{du}{dx},\quad \frac{d^2y}{dx^2}=\frac{d^2u}{dx^2}.$$

This proposition is proved exactly in the same way as that in last article, by means of Taylor's theorem. These are particular cases of a general proposition relating to the contact of curves which may be stated thus: If two curves have a common absciss and ordinate, and if the differential co-efficients of the first order of the ordinates be equal, no third curve passing through their intersection can go between them, unless the differential co-efficient of its ordinate, corresponding to the same absciss, be equal to the differential co-efficients of their ordinates. And if, besides their first differential co-efficients, their second differential co-efficients be equal, then no third curve passing through their intersection can go between them, unless the first and second differential co-efficients of its ordinate be equal to the first and second differential co-efficients of the two curves, and so on to differential co-efficients of all orders.

In fact, the two curves meet only in the point in which their ordinates are the same, and the equality of the differential co-efficients merely indicates that no other curve in which the same equality does not take place can pass between them.

From what has been shown, it appears that the contacts of curve lines may be distinguished into different orders. The degree of contact in which the ordinates and also the first differential co-efficients are equal, may be called a *Contact of the first order;* when, in addition to these, the second differential co-efficients are equal, it is a *Contact of the second order;* and so on.

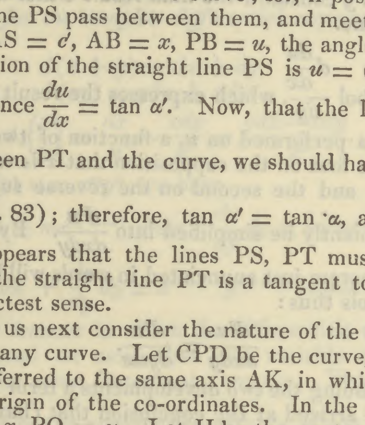
85. In illustration of this theory of contacts, let us consider the nature of the contact of any curve HPK (see fig. 6), with a straight line PT. Let A be the common origin of the co-ordinates. In the curve, let AB $= x$, PB $= y$. Its nature will be expressed by an equation $y = f(x)$. In the straight line, let TA $= c$, AB $= x$, PB $= v$, angle PTB $= \alpha$; the equation of the straight line is $v = (c + x) \tan \alpha$. The hypothesis that the curve and straight line have a common point, gives $y = v$; and the equation of the straight line, considering that c and α must be regarded as constants, gives $\frac{dv}{dx} = \tan \alpha$; now, by our theory, $\frac{dy}{dx} = \frac{dv}{dx}$, therefore $\frac{dy}{dx} = \tan \alpha$. This result coincides with what was found in art. 66; and it gives the sub-tangent

$$\mathrm{BT} = \frac{y}{\tan \alpha} = \frac{dx}{dy}\, y.$$

It is impossible that any straight line can pass between the straight line PT and the curve; for, if possible, let the straight line PS pass between them, and meet the axis in S. Put AS $= c'$, AB $= x$, PB $= u$, the angle PSB $= \alpha'$. The equation of the straight line PS is $u = (c' + x) \tan \alpha'$; and hence $\frac{du}{dx} = \tan \alpha'$. Now, that the line PS may pass between PT and the curve, we should have $\frac{du}{dx} = \frac{dv}{dx} = \frac{dy}{dx}$ (art. 83); therefore, $\tan \alpha' = \tan \alpha$, and $\alpha' = \alpha$; thus it appears that the lines PS, PT must coincide; therefore the straight line PT is a tangent to the curve, in the strictest sense.

86. Let us next consider the nature of the contact of a circle and any curve. Let CPD be the curve, and C′PD′ a circle referred to the same axis AK, in which A is the common origin of the co-ordinates. In the curve CPD let AQ $= x$, PQ $= y$. Let H be the centre of the circle; draw the radius PH, and produce it to meet the axis in N, and draw HI, HK perpendicular to PQ and AQ. Put AQ $= x$, PQ $= v$, these being co-ordinates of P any point in the circumference of the circle; and put AK $= \alpha$, HK $= \beta$, the co-ordinates of its centre; and PH $= r$ its radius.

Fig. 20.



Direct Method.

The equation of the curve CPD may be expressed generally by $y = f(x)$. And, since IH $= \alpha - x$, PI $= v - \beta$, and PH $= r$, the equation of the circle will be

$$(\alpha - x)^2 + (v - \beta)^2 = r^2 \ldots\ldots\ldots\ldots\ldots (1)$$

A contact of the first degree requires that $\frac{dy}{dx} = \frac{dv}{dx}$. Now, observing that α, β, and r must be considered as constants, we have $\frac{dv}{dx} = \frac{\alpha - x}{v - \beta}$, hence and because $y = v$,

$$\frac{dy}{dx} = \frac{\alpha - x}{y - \beta} \ldots\ldots\ldots\ldots\ldots\ldots\ldots (2)$$

The second side of this formula expresses the trigonometrical tangent of the angle PHI or PNQ. Hence (art. 65) the line PN is a normal to the curve at P, and the circle and curve have a common tangent at that point. By a second differentiation

$$\frac{d^2v}{dx^2} = -\frac{1}{v - \beta} - \frac{\alpha - x}{(v - \beta)^2} \cdot \frac{dv}{dx} = -\frac{(\alpha - x)^2 + (v - \beta)^2}{(v - \beta)^3}.$$

Now, that the circle and curve may have a contact of the second degree of closeness, it is necessary that $\frac{d^2v}{dx^2} = \frac{d^2y}{dx^2}$, therefore, observing that $v = y$, and that $(\alpha - x)^2 + (v - \beta)^2 = r^2$, we have

$$\frac{d^2y}{dx^2} = \frac{-r^2}{(y - \beta)^3} \ldots\ldots\ldots\ldots\ldots\ldots\ldots (3)$$

The three equations (1), (2), (3) serve to determine r, the radius of the circle, and α, β the co-ordinates of its centre. From the first and second we get

$$\alpha - x = \frac{r\,dy}{(dx^2 + dy^2)^{\frac{1}{2}}}; \quad y - \beta = \frac{r\,dx}{(dx^2 + dy^2)^{\frac{1}{2}}};$$

and from these, and equation (3), we get

$$r = -\frac{(dx^2 + dy^2)^{\frac{3}{2}}}{dx\,d^2y};$$

$$\alpha = x - \frac{dy}{dx} \cdot \frac{dx^2 + dy^2}{d^2y}; \quad \beta = y + \frac{dx^2 + dy^2}{d^2y}.$$

These expressions for α, β, and r determine the position and magnitude of the circle; they are manifestly identical with the radius of the circle of equal curvature, and the co-ordinates of its centre formerly found (art. 78 and 79). Hence we conclude, that the circle of equal curvature with a curve in any point, determined by the theory of evolutes, is identical with a circle, having with the curve a contact of the second order.

And since it appears that only one circle can have with a curve a contact of the second order, and that no circle can pass between that circle and the curve, therefore the same must be true of the circle of equal curvature, found by the theory of evolutes.

87. From what has been shown in regard to the degrees of contact of a straight line and circle with a curve, it appears that these depend on the number of constants which enter into the equation of the touching line. The equation of a straight line contains two constants, and it admits of one order of contact only. The equation of a circle has three constants, and it admits of a contact of the second order. It is easy to see that the number of differential co-efficients that can be made equal in the two curves will always be one less than the number of constants in the touching curve. The equation of a parabola is $y = \alpha + \beta x + \gamma x^2$. This and the differential equations which may be deduced from it serve to determine the three constants α, β, γ, and thence the parabola of equal curvature; but since there are only two differential co-efficients, the parabola can have a contact of the first and

also of the second order with any curve, but no higher order of contact. A cubic parabola, whose equation is $y = \alpha + \beta x + \lambda x^2 + \delta x^3$, may, however, have a contact of the third order, because it involves four constants, and so on.

Development and Differentiation of Functions containing two Variables.

88. Let u be a function of two independent variables, x and y; for example, $u = ax^2 + bxy + cy^2$, and in general $u = f(x, y)$. Suppose now that x changes its value, and becomes $x + h$, and that y becomes $y + k$, so that u' being the new value of the function, $u' = f(x+h, y+k)$. It is proposed to expand u' into a series of terms proceeding by the integer powers of h and k. In particular cases the method of proceeding is obvious; a general formula may be found by Taylor's theorem as follows.

It is easy to see that the result will be the same whether we substitute at once $x + h$ for x, and $y + k$ for y, in the function u, and then expand it; or, otherwise, first substitute $x + h$, then expand the function, according to the powers of h, and in this first result put $y + k$ for y, and afterwards expand it into terms proceeding by the powers of k; or we may reverse this process, beginning with the expansion according to the powers of k, and ending with that proceeding by the powers of h.

Resuming the function $u = f(x, y)$; when x becomes $x + h$, we have by Taylor's theorem $f(x + h, y) =$

$$u + \frac{du}{dx}h + \frac{d^2u}{dx^2}\frac{h^2}{1.2} + \frac{d^3u}{dx^3}\frac{h^3}{1.2.3} + \&c.$$

the differentials being taken upon the supposition that x is variable, and y a constant. And in this series y is contained only in the function u, and the differential co-efficients $\frac{du}{dx}, \frac{d^2u}{dx^2}$, &c.

Suppose now that y becomes $y + k$, then, in the series, the function u becomes

$$u + \frac{du}{dy}k + \frac{d^2u}{dy^2}\frac{k^2}{1.2} + \frac{d^3u}{dy^2}\frac{k^3}{1.2.3} + \&c.;$$

the function $\frac{du}{dx}$ becomes

$$\frac{du}{dx} + \frac{d\frac{du}{dx}}{dy}k + \frac{d^2\frac{du}{dx}}{dy^2}\frac{k^2}{1.2} + \frac{d^3\frac{du}{dx}}{dy^3}\frac{k^3}{1.2.3} + \&c.;$$

the function $\frac{d^2u}{dx^2}$ becomes

$$\frac{d^2u}{dx^2} + \frac{d\frac{d^2u}{dx^2}}{dy}k + \frac{d^2\frac{d^2u}{dx^2}}{dy^2}\frac{k^2}{1.2} + \frac{d^3\frac{d^2u}{dx^2}}{dy^3}\frac{k^3}{1.2.3} + \&c.;$$

the function $\frac{d^3u}{dx^3}$ becomes

$$\frac{d^3u}{dx^3} + \frac{d\frac{d^3u}{dx^3}}{dy}k + \frac{d^2\frac{d^3u}{dx^3}}{dy^2}\frac{k^2}{1.2} + \frac{d^3\frac{d^3u}{dx^3}}{dy^3}\frac{k^3}{1.2.3} + \&c.;$$

and in the differentiation of the functions $u, \frac{du}{dx}, \frac{d^2u}{dx^2}$, &c., y is taken as the variable, and x as a constant. By making the proper substitutions, we have $f(x + h, y + k)$ expressed by the series

$$u + \frac{du}{dy}k + \frac{d^2u}{dy^2}\frac{k^2}{1.2} + \&c.$$

$$+ \frac{du}{dx}h + \frac{d\frac{du}{dx}}{dy}hk + \&c.$$

$$+ \frac{d^2u}{dx^2}\frac{h^2}{1.2} + \&c.$$

$$+ \&c.$$

If the substitutions of $x + h$ for x, and $y + k$ for y, had been made in an inverse order, we would have had $f(y + k, x + h)$ equal to

$$u + \frac{du}{dx}h + \frac{d^2u}{dx^2}\frac{h^2}{1\cdot2} + \&c.$$

$$+ \frac{du}{dy}k + \frac{d^2\frac{du}{dy}}{dx}hk + \&c.$$

$$+ \frac{d^2u}{dy^2}\frac{k^2}{1\cdot2} + \&c.$$

The order in which the substitutions are made being arbitrary, the two developments of $f(x + h, y + k)$ must be identical, consequently the terms containing the same products of h and k must be equal. Thus, passing over the terms which are the same, we have

$$\frac{d\frac{du}{dx}}{dy} = \frac{d\frac{du}{dy}}{dx}.$$

89. This formula proves an important theorem in the calculus, namely, if a function u of two independent variables x and y be twice differentiated, first, on the hypothesis that x is variable and y constant, and then the result on the supposition that y is variable and x constant. And again, if the order of the differentiations be reversed, that is, if y be made variable and x constant, and then x variable and y constant, the final result either way will be the very same.

The symbol $\frac{d\frac{du}{dx}}{dy}$, which expresses the result of two differentiations performed on u, a function of two variables x and y (the first on the supposition that x is variable and y constant, and the second on the reverse supposition), may conveniently be simplified into $\frac{d^2u}{dxdy}$. By this notation the theorem just enunciated in words will be expressed in symbols thus:

$$\frac{d^2u}{dxdy} = \frac{d^2u}{dydx}.$$

By continuing the two developments a term farther, we would have arrived at the conclusion that (having regard to the notation just premised),

$$\frac{d^3u}{dxdydx} = \frac{d^3u}{dx^2dy} = \frac{d^3u}{dydx^2};$$

$$\text{and that } \frac{d^3u}{dxdy^2} = \frac{d^3u}{dy^2dx}, \&c.$$

Suppose, for example, that $u = x^3 y^5$, then

$$\frac{du}{dx} = 3\,x^2y^5, \qquad \frac{du}{dy} = 5\,x^3y^4,$$

$$\frac{d^2u}{dxdy} = 15\,x^2y^4, \quad \frac{du}{dydx} = 15\,x^2y^4,$$

$$\frac{d^3u}{dx^2dy} = 30\,xy^4, \quad \frac{d^3u}{dydx^2} = 30\,xy^4.$$

Adopting now the abbreviated notation, when $u = f(x, y)$, we have $f(x + h, y + k) =$

$$u + \frac{du}{dx}h + \frac{d^2u}{dx^2}\frac{h^2}{2} + \frac{d^3u}{dx^3}\frac{h^3}{2\,.\,3} + \&c.$$

$$+ \frac{du}{dy}k + \frac{d^2u}{dydx}hk + \frac{d^3u}{dydx^2}\frac{hk^2}{2} + \&c$$

$$+\frac{d^2u}{dy^2}\frac{k^2}{2}+\frac{d^3u}{dy^2dx}\frac{hk^2}{2}+\text{\&c.}$$

$$+\frac{d^3u}{dy^3}\frac{k^3}{2\,.\,3}+\text{\&c.}$$

This is the complete development of the function u.

90. Supposing u to be any function of x, and that x becomes $x+h$, by which u becomes $u+ph+qh^2+$&c., or (considering h as the *differential* of x) $u+pdx+qdx^2+$ &c. We have defined the *differential* of u to be the term pdx, viz. that which contains the simple power of h or dx, and called the function p, the *differential co-efficient*, representing it by $\frac{du}{dx}$. We may now extend these definitions to $f(x, y)$, a function of two variables, and changing h into dx and k into dy in the development of the function, we shall have

$$df(x, y)=du=\frac{du}{dx}dx+\frac{du}{dy}dy.$$

From this it appears that the *complete* differential of a function of two variables consists of two parts, viz. $\frac{du}{dx}dx$, or the differential taken on the supposition that x alone is variable, and $\frac{du}{dy}dy$, or the differential taken when y only is variable.

We may also apply to functions of two variables the rules which have been given (art. 10–23) for those which depend only on one; and for this purpose *we must differentiate the function first with respect to one of its variables, and then with respect to another; and take the sum of the results for the complete differential required.* By this rule

$$d(x+y)=dx+dy$$
$$d(xy)=ydx+xdy,$$
$$d\left(\frac{x}{y}\right)=\frac{dx}{y}-\frac{xdy}{y^2}=\frac{ydx-xdy}{y^2}.$$

Again, let $u=x^my^n$, we have

$$\frac{du}{dx}dx=mx^{m-1}y^ndx,\quad \frac{du}{dy}dy=nx^my^{n-1}dy,$$

$$du=\frac{du}{dx}dx+\frac{du}{dy}dy=x^{m-1}y^{n-1}(mydx+nxdy).$$

91. The manner in which the differentials of functions which depend on more than one variable are written, gives rise to some important remarks. The expression $\frac{du}{dx}dx$ must not be confounded with du, which it might be if u contained only the variable x; the symbol $\frac{du}{dx}$ has in this case a particular meaning, and denotes the differential co-efficient taken on the hypothesis of x only being variable; or it is the quotient of the first term of the development of the difference taken on that supposition divided by the increment dx; and $\frac{du}{dy}dy$ signifies the same with respect to y.

The quantities $\frac{du}{dx}, \frac{du}{dy}$ are commonly called *partial differences* of the first order of the function u, and generally $\frac{d^{m+n}u}{dx^mdy^n}$ represents one of those of the order $m+n$, which arises by differentiating m times in respect of x, and n times in respect of y.

A function of a single variable has only one differential co-efficient of any order; but a function of two variables has two differential co-efficients for the first order, three for the second, &c. These may be deduced from the two first, beginning with

$$du=\frac{du}{dx}dx+\frac{du}{dy}dy;$$

then, taking the differentials of $\frac{du}{dx}$ and $\frac{du}{dy}$, which must be treated as functions of two variables, we have

$$d\frac{du}{dx}=\frac{d^2u}{dx^2}dx+\frac{d^2u}{dydx}dy,$$

$$d\frac{du}{dy}=\frac{d^2u}{dxdy}dx+\frac{d^2u}{dy^2}dy;$$

and since the second differential is nothing more than the differential of the first,

$$d^2u=\frac{d^2u}{dx^2}dx^2+2\frac{d^2u}{dxdy}dxdy+\frac{d^2u}{dy^2}dy^2.$$

Here dx and dy are considered as constant quantities, and the differential co-efficients whose denominators contain only the products of dx and dy differently arranged, are considered as identical. By a repetition of this process, an expression may be found for the third differential co-efficient of the function u, and so on to any differential.

92. What has been explained in respect of a function of two independent variables, will apply to a function of any number; thus, if $u=f(t, x, y, z)$, then,

$$du=\frac{du}{dt}dt+\frac{du}{dx}dx+\frac{du}{dy}dy+\frac{du}{dz}dz,$$

where the symbols

$$\frac{du}{dt}, \frac{du}{dx}, \frac{du}{dy}, \frac{du}{dz},$$

denote the differential co-efficients of the function u taken on the supposition that t or x or y or z alone varies.

This notation owes its origin to Fontaine. Euler feared that the differential co-efficient $\frac{du}{dx}$ might be confounded with the ratio of the complete differential du to the differential dx, which is equivalent to

$$\frac{\frac{du}{dt}dt+\frac{du}{dx}dx+\frac{du}{dy}dy+\frac{dz}{dz}dz}{dx},$$

he therefore denoted this ratio by $\frac{du}{dx}$, whilst he expresses the differential co-efficient found by supposing x alone variable by $\left(\frac{du}{dx}\right)$. The nature of the subject, however, in general shows which of the two is intended, and renders this distinction superfluous.

Of Changing the Independent Variable.

93. Supposing y to be any function of x, we have estimated every change in the magnitude y by that of the value of x, which has been supposed to vary in any way whatever. It is, however, sometimes convenient to reverse the hypothesis, and consider x as a function of y. We are now to investigate general rules, by which we may pass from the differentials of y, regarded as a function of x, to those of x considered as a function of y.

Let $y=f(x)$, and let us suppose that when x becomes $x+h$, y becomes $y+k$. By Taylor's theorem,

$$k=\frac{dy}{dx}h+\frac{d^2y}{dx^2}\frac{h^2}{2}+\frac{d^3y}{dx^3}\frac{h^3}{2\,.\,3}+\text{\&c.}\ldots\ldots\ldots\ldots\ldots(1)$$

On the reverse hypothesis, supposing $x = \mathrm{F}(y)$ a function of y, then, similarly,

$$h = \frac{dx}{dy}k + \frac{d^2x}{dy^2}\frac{k^2}{2} + \frac{d^3x}{dy^3}\frac{k^3}{2 \, . \, 3} + \&\text{c.} \ldots\ldots\ldots\ldots\ldots\ldots (2)$$

Let the value of k, as given by the first equation, be substituted in the second; and, in order to abridge, let us put $\frac{dy}{dx} = y'$, $\frac{d^2y}{dx^2} = y''$, &c.

also $\frac{dx}{dy} = x'$, $\frac{d^2x}{dy^2} = x''$, &c.; then we have

$$h = x'\left(y'h + y''\frac{h^2}{2} + y'''\frac{h^3}{2 \, . \, 3} + \&\text{c.}\right)$$

$$+ \frac{x''}{2}\left(y'h + y''\frac{h^2}{2} + y''\frac{h^3}{2 \, . \, 3} + \&\text{c.}\right)^2 + \&\text{c.}$$

Hence, by actually involving the series to the second, third, powers, &c. and bringing into one term like powers of h, we find

$$0 = (x'y' - 1)\,h + (x'y'' + x''y'^2)\frac{h^2}{2}$$

$$+ (x'y''' + 3x''y'y'' + x'''y')\frac{h^3}{3} + \&\text{c.}$$

Now, that this equation may be satisfied, the co-efficients of the powers of h must be each $= 0$; thus,

$$x'y' - 1 = 0, \quad x'y'' + x''y'^2 = 0,$$
$$x'y''' + 3x''y'y'' + x'''y' = 0, \ \&\text{c.}$$

These equations give us

$$y' = \frac{1}{x'}, \quad y'' = -\frac{x''}{x'^3}, \quad y''' = \frac{3x''^2}{x'^5} - \frac{x'''}{x'^4},$$

$$y^{\text{IV}} = \frac{15x''^3}{x'^7} + \frac{10x''x'''}{x'^6} - \frac{x^{\text{IV}}}{x'^5}, \ \&\text{c.}$$

Reversely, we have

$$x' = \frac{1}{y'}, \quad x'' = -\frac{y''}{y'^3}, \quad x''' = \frac{3y''^2}{y'^5} - \frac{y'''}{y'^4},$$

$$x^{\text{IV}} = \frac{15y''^3}{y'^7} + \frac{10y''y'''}{y'^6} - \frac{y^{\text{IV}}}{y'^5}, \ \&\text{c.}$$

As an application of these formulæ, we may transform the expression for the radius of curvature found (art. 78), on the hypothesis that y is a function of x, into another in which x is a function of y. Employing the notation of last article,

$$r = -\frac{(1 + y'^2)^{\frac{3}{2}}}{y''}.$$

Now by the formulæ $y' = \frac{1}{x'}$, and $y'' = -\frac{x''}{x'^3}$: this substitution being made, we obtain

$$r = \frac{(x'^2 + 1)^{\frac{3}{2}}}{x''} = \frac{(dx^2 + dy^2)^{\frac{3}{2}}}{dyd^2x}.$$

94. Instead of supposing that one of the two variables x, y, is a function of the other, it is sometimes convenient to regard both as functions of a third quantity. Thus, in geometry, supposing x and y to be the co-ordinates of a curve, we may consider the one as a function of the other; or we may consider both as functions of the angle which a tangent makes with the axis, which angle is then the independent variable. Or x and y denoting the co-ordinates of the path of a projectile, both may be considered as functions of t, the time of the motion.

Suppose that when t becomes $t + i$, x becomes $x + h$, and that y becomes $y + k$; to abridge, put x', x'', &c. for $\frac{dx}{dt}$, $\frac{d^2x}{dt^2}$, &c.; also y', y'', &c. for $\frac{dy}{dt}$, $\frac{d^2y}{dt^2}$, &c. and (y'), (y''), &c. for $\frac{dy}{dx}$, $\frac{d^2y}{dx^2}$, &c.

By Taylor's theorem,

$$y = f(x) \text{ gives } k = (y')\,h + (y'')\frac{h^2}{2} + \&\text{c.} \ldots\ldots (1)$$

$$y = \mathrm{F}(t) \text{ gives } k = y'i + y''\frac{i^2}{2} + \&\text{c.} \ldots\ldots\ldots\ldots\ldots (2)$$

$$x = \varphi(t) \text{ gives } h = x'i + x''\frac{i^2}{2} + \&\text{c.} \ldots\ldots\ldots\ldots\ldots (3)$$

The three increments k, h, i are generated together, therefore these equations must all hold true at the same time. Let the value of h, found from the third equation, be substituted in the first, then, putting the two values of k equal, we have

$$(y')\left\{x'i + x''\frac{i^2}{2} + \&\text{c.}\right\}$$

$$+ (y'')\left\{x'i + x''\frac{i^2}{2} + \&\text{c.}\right\}^2 + \&\text{c.}$$

$$= y'i + y''\frac{i^2}{2} + \&\text{c.}$$

Hence, by involution, and making the co-efficients of like powers of i equal to zero, as usual, we find

$$x'(y') = y', \quad x''(y') + x'^2(y'') = y'', \ \&\text{c.}$$

$$\text{therefore } (y') = \frac{y'}{x'} \qquad (y'') = \frac{y'' - x''(y')}{x'^2}, \ \&\text{c.}$$

As an example, let us take the formula for the radius of curvature, which, by the notation just premised, will be

$$r = -\frac{\{1 + (y')^2\}^{\frac{3}{2}}}{(y'')^2}.$$

By substituting for (y') and (y'') their values, it becomes

$$r = -\frac{(x'^2 + y'^2)^{\frac{3}{2}}}{x'y'' - y'x''};$$

and hence, putting $\frac{dx}{dt}$ for x', $\frac{dy}{dt}$ for y', $\frac{d^2x}{dt^2}$ for x'', and $\frac{d^2y}{dt^2}$ for y'', we get

$$r = \frac{(dx^2 + dy^2)^{\frac{3}{2}}}{dyd^2x - dxd^2y}.$$

The independent variable t does not appear in the formula; nevertheless, in its application, we must keep in mind the hypothesis by which it was found.

Of the Method of Infinitesimals.

95. The ideas which we have of infinity may be embodied in this proposition: *A quantity is not infinite so long as it admits of augmentation.* If, therefore, in the quantity $x + a$, we suppose x to become infinite, then a must be suppressed, otherwise it would be supposed that x might be increased by the quantity a, which is contrary to the definition. To show the consistency of the proposition, let there be an equation

$$\frac{1}{a} + \frac{1}{x} = \mathrm{M} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (1)$$

which being multiplied by the product ax, becomes

$$x + a = \mathrm{M}ax \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (2)$$

Suppose now that x increases until it becomes infinite; the fraction $\frac{1}{x}$, having reached its last degree of diminution, is reduced to 0, and therefore equation (1) becomes

$$\mathrm{M} = \frac{1}{a}, \text{ or } \mathrm{M}a = 1;$$

and this value being substituted in equation (2), it becomes $x+a=x$. This shows that when x is infinite, $x+a$ is reduced to x.

The quantity a, in respect of which x is infinite, is called an *infinitesimal* in respect of x.

Since we consider here only the ratios of quantities, the preceding demonstration holds good when x has a finite value, provided that a be infinitely small in respect of x. Thus, if we compare b, a finite quantity, with the fraction $\frac{b}{z}$, then, z being supposed to increase continually, $\frac{b}{z}$ will decrease, and may become smaller than any assignable quantity; and when z is infinite, the fraction is $=0$, so that, in comparison with b, it may be neglected.

The ratios of quantities are altogether independent of their absolute magnitude. The halves, or any like parts of quantities, have the same ratios as the wholes. The symbols we employ in our reasonings are not the representatives of absolute magnitudes, but of numbers, which have a reference to an unit; they therefore represent ratios only, and the absolute magnitudes of the terms of the ratios are never considered. The differentials of quantities are the ratios to which the ratios of the increments of the variables continually approach; these increments may have any magnitude whatever. Leibnitz supposed them to be infinitely small quantities. Upon this hypothesis a theory has been constructed, which, by following certain ascertained principles, has led to the discovery of the most recondite truths in geometry and physics.

96. The admission of infinitesimals into the mathematical sciences, necessarily leads to a succession of different orders of infinitesimals. In a circle the ratio of the diameter to the chord of an arc is the same as the ratio of the chord to the versed sine; therefore, if the chord be infinitely small in respect of the diameter, or an infinitesimal of the *first* order, the versed sine will be infinitely small in respect of the chord; and, consequently, in respect of the diameter, will be an infinitesimal of the *second* order. So also, in a series of continued proportionals, $1, x, x^2, x^3$, &c. of which the first term is finite, and the second, x, an infinitesimal of the first order, the third, x^2, will be of the second order, and the fourth, x^3, of the third, and so on. Upon the same principle, the product ab of two infinitesimals, a, b of the first order will be an infinitesimal of the second; for we may consider that $1:a=b:ab$, that is, ab is a fourth proportional to three quantities 1, a, and b, of which the first is finite. In like manner, the product of three infinitesimals of the first order, also the product of an infinitesimal of the first and of the second order, will be an infinitesimal of the third order.

97. When the infinitely small increments of quantities are once taken as their differentials, the different rules for differentiation are easily found.

Thus, if $u=xy$; then u, x, and y receiving the infinitely small augments du, dx, and dy, we have

$$u+du=(x+dx)(y+dy)=xy+xdy+ydx+dxdy;$$

and, taking from these equals the equals u and xy,

$$du=xdy+ydx+dxdy.$$

Now du, xdy, ydx are infinitesimals of the first order, and $dxdy$ is an infinitesimal of the second, therefore it is incomparably smaller, and in respect of the others ought to be rejected, so that we have simply

$$du=xdy+ydx.$$

98. In this theory a curve is considered as a polygon of an infinite number of sides, any one of which is the differential of the arc, therefore the differential of the arc will be the hypotenuse of a right-angled triangle, of which the sides are the differentials of the co-ordinates; and these being denoted by x and y, and the arc by z, we have $dz^2=dx^2+dy^2$. Proceeding on the same principles, if s denote the area of a curve, the increment of s or ds will be $ydx+\frac{1}{2}dxdy$; but the second part of this, viz. $\frac{1}{2}dxdy$, is a differential of the second order, and therefore infinitely less than ydx, which is of the first order, therefore we have simply $ds=ydx$, agreeing with the formula of art. 69.

In a circle, the infinitely small increments of the cosine, the sine, and the arc form a right-angled triangle similar to that formed by the sine, the cosine, and the radius, so that x being put for the arc, the radius being unity,

$1:\cos x=dx:d\sin x$, $1:\sin x=dx:-d\cos x$,
hence $d\sin x=dx\cos x$, and $d\cos x=-xdx$.

It is equally manifest, according to the infinitesimal theory, that the subtangent is a fourth proportional to dx (the differential of the absciss), dy (the differential of the ordinate), and y the ordinate; so that, as has been shown, art. 65,

$$\text{subtan}=\frac{\pm dy}{dx}y;$$

the positive sign being used if the absciss and ordinate increase together, otherwise the sign —.

The great facility which the theory of infinitesimals gives in the applications of the calculus to the higher geometry, and more especially to the doctrines of physics, is a high recommendation in its favour. Indeed, whatever view be taken of the subject, the mathematician will hardly be restrained from taking the shortest way he can find to the object he wishes to attain, and that is in general by the infinitesimal calculus. Accordingly we observe that M. Poisson, in the second edition of his *Traité de Mécanique*, distinctly premises that he will exclusively employ the method of *infiniment petits* throughout his work.

PART II.

INVERSE METHOD OF FLUXIONS, OR INTEGRAL CALCULUS.

99. The *inverse method of fluxions*, or *integral calculus*, treats of the analytic processes by which a function may be found, such, that being differentiated, it shall produce a given differential. This function has been called, by writers on fluxions, the *fluent* or *flowing quantity*; and by writers on the differential calculus, the *integral* of the proposed differential.

To find the integral of a differential is to *integrate* that differential; and the process by which the integral is found is called *integration*.

100. When an integral is proposed, its differential may always be found by general rules. There is however no direct rule by which we may return from the differential to the integral, except the obvious one of retracing the steps by which the differential has been deduced from the integral. When these are distinctly indicated, there is no difficulty; but in general the steps of calculation by which the differential might have been deduced from an integral are obliterated or unknown; or the differential may not have been a direct result of differentiation; and then there will be no traces to show how we may pass from it to the integral.

101. It is convenient to have a symbol by which the integral of a differential may be indicated without regard to its particular form: for this purpose the letter $\int$ (the initial letter of the word *sum*) is employed. Thus, the integral of the differential $\mathrm{X}dx$ is expressed by the symbol $\int \mathrm{X}dx$.

102. We have seen (art. 9) that in differentiating an expression of the form $\mathrm{X}\pm\mathrm{C}$, which is the sum or dif-

ference of a variable function and a constant quantity, the constant disappears; therefore, reversely, in taking the integral of any differential, the constant, C, must be added to make the integral complete. This indeterminate quantity has been called by early English writers the *correction* of the fluent or integral, but now it is generally called the *arbitrary constant.* It may be written either with the sign $+$ or $-$; its value is to be determined, as will appear hereafter, from the particular problem under consideration.

Integration of Rational Functions involving one Variable.

103. The general form of a differential of the first order of a function is Xdx, where X denotes any function of a single variable x. Now this function may have various forms, and may be rational or irrational.

The rational forms of the function may be

$$Ax^m + Bx^n + Cx^p + \&c. = U,$$

$$\frac{Ax^m + Bx^n + Cx^p + \&c.}{A'x^{m'} + B'x^{n'} + C'x^n + \&c.} = \frac{U}{V},$$

the first of which is integral and the second fractional.

Irrational functions have the form

$$UV^{\frac{m}{n}},$$

and transcendental functions,

$$f(U, \text{l. } U),\ f(U, \sin v), \&c.$$

104. The simplest case of a rational function is ax^n, the differential of which is $nax^{n-1}dx$; therefore, putting $m = n - 1$, so that $n = m + 1$, we have,

when $dy = ax^m dx$,

$$\text{then } y = \int ax^m dx = \frac{a}{m+1}\, x^{m+1} + C.$$

Hence this rule: *To integrate a differential of one term, such as* ax^n dx, *we must increase the exponent of the variable by an unit, and then divide by the new exponent and by* dx.

We may give the indeterminate constant C the form $-\frac{ab^{n+1}}{n+1}$, and then we shall have

$$\int ax^n dx = \frac{a(x^{n+1} - b^{n+1})}{n+1}.$$

This is the form the integral should have, if it has the property of vanishing in the particular case of $x = b$.

105. There is a particular case to which the general rule of last article will not immediately apply; it is that in which $n = -1$; in that case it gives

$$\int \frac{adx}{x} = \int ax^{-1} dx = \frac{a(x^0 - b^0)}{0} = \frac{1-1}{0} = \frac{0}{0}.$$

From this no conclusion can be drawn, and the integral has been said to *fail.* This, however, is only in appearance; for, putting $n+1 = m$, we have (art. 35)

$$x^m = 1 + (\text{l. } x)\, m + (\text{l. } x)^2 \frac{m^2}{1\cdot 2} + \&c.$$

$$b^m = 1 + (\text{l. } b)\, m + (\text{l. } b)^2 \frac{m^2}{1\cdot 2} + \&c.$$

$$x^m - b^m = \{\text{l. } x - \text{l. } b\}\, m + \{(\text{l. } x)^2 - (\text{l. } b)^2\} \frac{m^2}{1\cdot 2} + \&c.$$

$$\frac{x^m - b^m}{m} = \text{l. } x - \text{l. } b + \{ (\text{l. } x)^2 - (\text{l. } b)^2 \frac{m}{2} + \&c.$$

This, when $n+1 = m = 0$ and $n = -1$, gives

$$\int \frac{adx}{x} = a\{\text{l. } x - \text{l. } b\} = a \text{ l. } x + C.$$

This result coincides entirely with the expression for the differential of the logarithm of a number (art. 20).

106. By the rule of art. 104 it is evident that if

$$dy = ax^m dx + bx^n dx + cx^p dx,$$

$$\text{then, } y = \frac{ax^{m+1}}{m+1} + \frac{bx^{n+1}}{n+1} + \frac{cx^{p+1}}{p+1} + C.$$

This is true, however many terms there may be in the differential: the indeterminate constant C represents the aggregate of all the constants of the integrals of the several terms.

In general, since (art. 15),

$$d(u + v - z) = du + dv - dz,$$

$$\text{therefore } u + v - z = \int du + \int dv - \int dz;$$

and in general, P, Q, R, being any functions of x,

$$\int (Pdx + Qdx - Rdx) = \int Pdx + \int Qdx - \int Rdx.$$

107. It has been found that u and v being any functions of a variable, $d(uv) = udv + vdu$, therefore

$$\int udv = uv - \int vdu.$$

In like manner, from the differential of a fraction we find

$$\int u \frac{dv}{v^2} = -\frac{u}{v} + \int \frac{du}{v}.$$

Since $d(au) = adu$, we may conclude that

$$\int aXdx = a \int Xdx.$$

108. To integrate the differential

$$dy = (ax + b)^m dx,$$

we may expand the given power, and integrate the terms of the result separately; otherwise, make $z = ax + b$, then

$$x = \frac{z-b}{a},\quad dx = \frac{dz}{a}.$$

By substitution, we have now $dy = \frac{z^m dz}{a}$, and by integration,

$$y = \frac{z^{m+1}}{a(m+1)} + C = \frac{(ax + b)^{m+1}}{a(m+1)} + C.$$

The integral of $dy = (ax^n + b)^m\, x^{n-1}\, dx$ may be found in the same way, by putting $ax^n + b = z$; we thus get

$$y = \frac{(ax^n + b)^{m+1}}{na(m+1)} + C.$$

109. We shall next consider fractional functions, and begin with the simple case of $dy = \frac{Ax^m dx}{(ax+b)^n}$; making $z = ax + b$, we find

$$x = \frac{z-b}{a},\quad dx = \frac{dz}{a},$$

and consequently

$$dy = \frac{A(z-b)^m dz}{a^{m+1}\, z^n}.$$

By expanding $(z - b)^m$ into a series, then multiplying the terms by dz, and dividing by z^n, the differential will be transformed into a series of terms of the form $cz^p dz$, which may be integrated severally by the rule (art 104). As a particular example, let $m = 3$, $n = 2$, then

$$dy = \frac{A(z - b)^3 dz}{a^4 z^2}$$

$$= \frac{A}{a^4}\left\{zdz - 3bdz + 3b^2 z^{-1} dz - b^3 z^{-2} dz\right\}:$$

Hence, integrating by the rule,

$$y = \frac{A}{a^4}\left\{\frac{z^2}{2} - 3bz + 3b^2 \text{ l. } z + b^3 z^{-1}\right\} + C.$$

We now substitute for z its value, and find

$$y = \frac{A}{a^4}\left\{\begin{matrix}\frac{1}{2}(ax + b)^2 - 3b(ax + b) \\ + 3b^2 \text{ l. } (ax + b) + \dfrac{b^3}{ax + b}\end{matrix}\right\} + C.$$

110. All differentials which are rational fractions may be reduced to this form,

$$\frac{(Ax^{n-1} + Bx^{n-2} + Cx^{n-2} \ldots + T)dx}{x^n + A' x^{n-1} + B' x^{n-2} \ldots + T'}.$$

The general method of integrating such a differential consists in decomposing it into others whose denominators are more simple, which are called *partial fractions*. These are obtained as follows.

Assume the denominator of the proposed fraction equal to *zero*, thus forming the equation

$$x^n + A' x^{n-1} + B' x^{n-2} \ldots + T' = 0.$$

Let the roots of this equation be

$$x = -a,\ x = -a',\ x = -a'',\ x = -a''', \&c.$$

and supposing them all different, the first side of the equation will be (ALGEBRA, art. 99) the product of n factors,

$$x + a,\ x + a',\ x + a'',\ x + a''', \&c.$$

We now assume that the proposed fraction is the sum of the fractions

$$\frac{Ndx}{x + a}, \frac{N'dx}{x + a'}, \frac{N''dx}{x + a''}, \&c.$$

of which the denominators are the factors of the proposed fraction, and the numerators are undetermined constants. These being reduced to a common denominator, and added, the result will be a fraction identical with the proposed fraction; and by putting the co-efficients of like powers of x in their numerators equal to one another, a series of equations will be had, by which the undetermined constants N, N′, N″, &c. may be found.

As an example, suppose the differential to be integrated is

$$\frac{(Ax^2 + Bx + C)\,dx}{x^3 + A'x^2 + B'x + C'},$$

and that by the resolution of an equation we know that

$$x^3 + A'x^2 + B'x + C' = (x + a)(x + a')(x + a'').$$

setting aside dx, we assume that the fraction is equivalent to

$$\frac{N}{x + a} + \frac{N'}{x + a'} + \frac{N''}{x + a''}.$$

The sum of these is

$$\frac{N(x+a')(x+a'')+N'(x+a)(x+a'')+N''(x+a)(x+a')}{(x + a)(x + a')(x + a'')}.$$

The numerator of this fraction is, by multiplying its factors,

$$(N+N'+N'')x^2+\{N(a'+a'')+N'(a+a'')+N''(a+a')\}x$$
$$+ Na'a'' + N'aa'' + N''aa';$$

and as this must be equal to the numerator of the proposed differential, whatever be the value of x, the co-efficients of like powers of x will be equal (art. 18); hence we have these three equations,

$$N + N' + N'' = A.$$
$$N(a' + a'') + N'(a + a'') + N''(a + a') = B,$$
$$Na'a'' + N'aa'' + N''aa' = C;$$

which are only of the first degree with respect to the undetermined quantities N, N′, N′. Resolving these equations, we find N, N′, N″, and have

$$\frac{(Ax^2 + Bx + C)dx}{x^3 + A'x^2 + B'x + C'}$$
$$= \frac{Ndx}{x + a} + \frac{N'dx}{x + a'} + \frac{N''dx}{x + a''}.$$

Making $x + a = z$, we have $dx = dz$, and $\frac{Ndx}{x + a} = \frac{Ndz}{z}$, the integral of which is $N \text{ l. } z = N \text{ l. } (x + a)$; similarly,

$$\int\frac{N'dx}{x + a'} = N' \text{ l. } (x + a); \int\frac{N''dx}{x + a'} = N'' \text{ l. } (x + a'').$$

So that we have now

$$\int\frac{(Ax^2 + B x + C)dx}{x^3 + A'x^2 + B'x + C'}$$
$$= N \text{ l.} (x + a) + N \text{ l.} (x + a') + N \text{ l.} (x + a'') + \text{const.}$$
$$\text{l. } \{(x + a)^{N} \cdot (x + a')^{N'} \cdot (x + a'')^{N''}\} + \text{const.}$$

This process, which may be extended to all rational fractions whose denominators are decomposable into unequal factors of the *first* degree, has no difficulty, independent of the decomposition of the denominator into its factors, which, however, requires the numerical resolution of equations.

111. If some of the factors of the denominator of the proposed fraction are equal, the process will require to be modified to suit that case. Suppose the denominator $x^n + A'x^{n-1} +$, &c.... $+ T'$ to contain a factor $(x + a)^p$, then, for every such factor, it will be necessary to assume a partial fraction of the form

$$\frac{(Px^{p-1} + Qx^{p-2} +, \&c.... + Y)dx}{(x + a)^p}.$$

This and the other partial fractions being reduced to a common denominator, and added, and the terms of the numerator in the result being put equal to those of the numerator of the proposed differential, as before, as many independent equations will be obtained as there are co-efficients to be determined.

112. It is not difficult to see that the partial fraction suited to the case of equal factors may be transformed into an expression of the form

$$\frac{Ndx}{(x + a)^p} + \frac{N'dx}{(x + a)^{p-1}} \ldots + \frac{N''dx}{x + a};$$

therefore we may at once substitute this instead of the equivalent single fraction. We shall now have to integrate a series of differentials of the form

$$\frac{Ndx}{(x + a)^p},$$

which, by making $x + a = z$, and therefore $dx = dz$, gives

$$\int\frac{Ndx}{(x + a)^p} = \int\frac{Ndz}{z^p} = \frac{Nz^{-p+1}}{1-p}$$
$$= \frac{N}{(1-p)(x + a)^{p-1}}.$$

These will be all algebraical except the last, $\int\frac{Ndx}{x + a}$, which will involve a logarithm.

113. If there be imaginary factors, these will occur in pairs of the form $x + \alpha + \beta\sqrt{-1}$, $x + \alpha - \beta\sqrt{-1}$,

Inverse Method.

and their product will be $x^2 + 2ax + x^2 + \beta^2$. In this case the best way to proceed will be to resolve the denominator of the proposed differential into real factors of the first and of the second degree, which is always possible (see EQUATIONS). If there be several pairs of these imaginary factors, each pair the same, the denominator of the proposed differential will have factors of the form $(x^2 + 2ax + \alpha^2 + \beta^2)^q$. Then, for the single factor $x^2 + 2ax + \alpha^2 + \beta^2$, we must assume, in addition to the partial fractions, for factors of the first degree, one of this form,

$$\frac{(Kx + L)dx}{x^2 + 2ax + \alpha^2 + \beta^2};$$

and for factors of the second form, this fraction,

$$\frac{(Qx^{2q-1} + Rx^{2q-2} \ldots + Y')\,dx}{(x^2 + 2ax + \alpha^2 + \beta^2)^q};$$

or, instead of this, a series of fractions,

$$\frac{(Kx + L)\,dx}{(x^2 + 2ax + \alpha^2 + \beta^2)^q} + \frac{(K'x + L')dx}{(x^2 + 2ax + \alpha^2 + \beta^2)^{q-1}}$$
$$\ldots\ldots\ldots\ldots\ldots\ldots + \frac{(K'''x + L''')dx}{x^2 + 2ax + \alpha^2 + \beta^2};$$

the co-efficients to be determined, as before explained.

114. To integrate the fraction

$$\frac{(Kx + L)\,dx}{x^2 + 2ax + \alpha^2 + \beta^2},$$

we observe that $x^2 + 2ax + \alpha^2 + \beta^2 = (x + \alpha)^2 + \beta^2$; and if we make $x + \alpha = z$, then

$$\frac{(Kx + L)dx}{(x + \alpha)^2 + \beta^2} = \frac{(Kz + L - K\alpha)dz}{z^2 + \beta^2}$$
$$= \frac{Kzdz}{z^2 + \beta^2} + \frac{L'dz}{z^2 + \beta^2}.$$

Here L' is put for the constant quantity $L - K\alpha$. Now, the integral of the first of these differentials may be expressed by a logarithm; for, making $z^2 = u$, we have $zdz = \frac{1}{2}du$, which gives

$$\int \frac{Kzdz}{z^2 + \beta^2} = \frac{K}{2}\int\frac{du}{u} = K\tfrac{1}{2}\,\mathrm{l}.\,u = K\,\mathrm{l}.\sqrt{z^2 + \beta^2}.$$

With respect to the second part, we make $z = \beta v$, then,

$$\frac{L'dz}{z^2 + \beta^2} = \frac{L'}{\beta}\,\frac{dv}{v^2 + 1}.$$

But we have found (art. 23) that $\frac{dv}{v^2 + 1}$ is the differential of the arc whose tangent is v, which is expressed by $\tan^{-1} v$, therefore

$$\int \frac{L'}{\beta}\cdot\frac{dv}{v^2 + 1} = \frac{L'}{\beta}\tan^{-1} v + \text{const.}$$
$$= \frac{L'}{\beta}\tan^{-1}\frac{z}{\beta} + \text{const.}$$

Adding now these results, we get

$$\int \frac{(Kz + L')dz}{z^2 + \beta^2} = K\,\mathrm{l}.\sqrt{z^2 + \beta^2} + \frac{L'}{\beta}\tan^{-1}\frac{z}{\beta} + \text{const.}$$

When the value of z and L' are replaced, we have

$$\int \frac{(Kx + L)dx}{x^2 + 2ax + \alpha^2 + \beta^2} = \text{const.}$$
$$+ K\,\mathrm{l}.\sqrt{x^2 + 2ax + \alpha^2 + \beta^2} + \frac{L - K\alpha}{\beta}\tan^{-1}\frac{x + \alpha}{\beta}.$$

115. To integrate the differential

$$\frac{(Kx + L)dx}{(x^2 + 2ax + \alpha^2 + \beta^2)^q},$$

we shall at once make $x + \alpha = z$, and $L - K\alpha = L'$. By this the differential is transformed to

$$\frac{(Kz + L')dz}{(z^2 + \beta^2)^q} = \frac{Kzdz}{(z^2 + \beta^2)^q} + \frac{L'dz}{(z^2 + \beta^2)^q}.$$

To transform the first part, we make $z^2 + \beta^2 = u$, so that $zdz = \frac{du}{2}$, and consequently,

$$\int \frac{Kzdz}{(z^2 + \beta^2)^q} = \frac{K}{2}\int\frac{du}{u^q} = \frac{K}{2}\cdot\frac{u^{-q+1}}{1 - q}.$$

To integrate the second part, we assume the equation

$$\int \frac{dz}{(z^2 + \beta^2)^q} = \frac{Gz}{(z^2 + \beta^2)^{q-1}} + H\int\frac{dz}{(z^2 + \beta^2)^{q-1}};$$

that is, we assume the integral to be equal to an algebraic quantity, together with another integral whose denominator is less by an unit than the first. We now differentiate the terms of the assumed equation, observing that the removal of $\int$, the sign of an integral, is equivalent to the differentiation of that integral; we also reject such factors as are common to all the terms of the result, and thus have

$$1 = G\,(z^2 + \beta^2) - 2\,(q - 1)\,Gz^2 + H\,(z^2 + \beta^2);$$
$$\text{and } \{(3 - 2q)\,G + H\}\,z^2 + (G + H)\,\beta^2 - 1 = 0.$$

Now, that z may remain undetermined, we must have

$$(G + H)\,\beta^2 - 1 = 0, \quad (3 - 2q)\,G + H = 0.$$

From these equations, we find

$$G = \frac{1}{(2q - 2)\beta^2}, \qquad H = \frac{2q - 3}{(2q - 2)\beta^2}.$$

The values of G and H being substituted in our assumed equation, it becomes

$$\int \frac{dz}{(z^2 + \beta^2)^q} = \frac{1}{(2q - 2)\beta^2}\;\frac{z}{(z^2 + \beta^2)^{q-1}},$$
$$+ \frac{2q - 3}{(2q - 2)\beta^2}\int\frac{dz}{(z^2 + \beta^2)^{q-1}}.$$

This formula gives the means of depressing the index of the denominator of the proposed fraction; for, putting $q - 1$ instead of q, we find

$$\int \frac{dz}{(z^2 + \beta^2)^{q-1}} = \frac{1}{(2q - 4)\beta^2}\;\frac{z}{(z^2 + \beta^2)^{q-2}},$$
$$+ \frac{2q - 5}{(2q - 4)\beta^2}\int\frac{dz}{(z^2 + \beta^2)^{q-2}};$$

and again, putting $q - 2$ for q, we get

$$\int \frac{dz}{(z^2 + \beta^2)^{q-2}} = \frac{1}{(2q - 6)\beta^2}\;\frac{z}{(z^2 + \beta^2)^{q-3}},$$
$$+ \frac{2q - 7}{(2q - 6)\beta^2}\int\frac{dz}{(z^2 + \beta^2)^{q-3}}.$$

In this way the integral $\int\frac{dz}{(z^2 + \beta^2)^q}$ is expressed by an algebraic quantity, and another integral, $\int\frac{dz}{(z^2 + \beta^2)^{q-1}}$; and this last by another algebraic quantity, and the integral $\int\frac{dz}{(z^2 + \beta^2)^{q-2}}$; and so on, until we come to the integral $\int\frac{dx}{z^2 + \beta^2}$, which is known, and expressible by the arc of a circle. Here the process must stop; for the next transformation would involve the integral $\int\frac{dx}{(z^2 + \beta^2)^0}$, with

Inverse Method.

an infinite co-efficient, from which no conclusion can be drawn. Here we see the application of a method of integration at once fertile and elegant.

From what has been explained, it appears that differentials which are rational fractions may be always integrated either algebraically or by means of logarithms or circular arcs; all that is necessary is to decompose them into partial fractions, whose denominators are either binomial or trinomial quantities.

116. We shall now give some examples of the integration of differentials which are rational fractions.

1. Let the differential be $\frac{adx}{x^2-a^2}$.

In this case the denominator $x^2-a^2=(x-a)(x+a)$; we therefore assume

$$\frac{adx}{(x-a)(x+a)}=\left\{\frac{A}{x-a}+\frac{B}{x+a}\right\}dx.$$

We now reduce the second side to a single fraction, and, leaving out dx, have

$$\frac{a}{(x-a)(x+a)}=\frac{(A+B)x+(A-B)a}{(x-a)(x+a)};$$

therefore $a=(A+B)x+(A-B)a$.

Now, x being indeterminate, according to the principle of art. 18, we must have

$$(A-B)a=a, \quad A+B=0;$$

these equations give $A=\frac{1}{2}$, $B=-\frac{1}{2}$; the proposed differential is now

$$\frac{adx}{x^2-a^2}=\frac{1}{2}\frac{dx}{x-a}-\frac{1}{2}\frac{dx}{x+a};$$

and, by integrating,

$$\int\frac{adx}{x^2-a^2}=\tfrac{1}{2}\,\text{l.}\,(x-a)-\tfrac{1}{2}\,\text{l.}\,(x+a)+C,$$

$$=\tfrac{1}{2}\,\text{l.}\,\frac{x-a}{x+a}+C=\text{l.}\sqrt{\frac{x-a}{x+a}}+C.$$

2. Let the differential be $\frac{a^3+b^2x^2}{a^2x-x^3}dx$.

The factors of the denominator are x and a^2-x^2, which last resolves into $(a-x)(a+x)$; therefore, leaving out dx, we assume

$$\frac{a^3+bx^2}{x(a-x)(a+x)}=\frac{A}{x}+\frac{B}{a-x}+\frac{C}{a+x}.$$

The second side of this equation, by reducing its terms to a common denominator, and adding, is

$$\frac{Aa^2+a(B+C)x+(B-A-C)x^2}{x(a-x)(a+x)}.$$

By equating the co-efficients of the powers of x, we have

$$Aa^2=a^3, \quad a(B+C)=0, \quad B-A-C=b.$$

Here there are three unknown quantities, viz. A, B, C, and three simple equations, therefore they may be found, as taught in ALGEBRA, sect. viii.; and accordingly we have

$$A=a, \quad B=\tfrac{1}{2}(a+b), \quad C=-\tfrac{1}{2}(a+b),$$

$$\frac{a^3+bx^2}{a^2x-x^3}dx=\frac{adx}{x}+\frac{a+b}{2(a-x)}dx-\frac{a+b}{2(a+x)}dx;$$

and, integrating,

$$\int\frac{a^3+bx^2}{a^2x-x^3}dx=a\,\text{l.}\,x-\frac{a+b}{2}\,\text{l.}\,(a-x)$$

$$-\frac{a+b}{2}\,\text{l.}\,(a+x)+C.$$

By the nature of logarithms l. P + l. Q = l. (PQ) and n l. P = l. P^n; hence the integral may be otherwise expressed thus,

$$\int\frac{a^3+bx^2}{a^2x-x^3}dx=\text{l.}\,\frac{x^a}{(a^2-x^2)^{\frac{1}{2}(a+b)}}+C.$$

3. Let the differential be $\frac{3x-5}{x^2-6x+8}dx$.

To resolve the denominator into simple factors, we make $x^2-6x+8=0$, and find the roots of this equation to be $x=2$, and $x=4$; therefore, $x^2-6x+8=(x-2)(x-4)$. To decompose the fraction, leaving out dx, we now assume

$$\frac{3x-5}{(x-2)(x-4)}=\frac{A}{x-2}+\frac{B}{x-4},$$

$$=\frac{(A+B)x-4A-2B}{(x-2)(x-4)}.$$

Hence, equating the like terms in the numerators, we have

$$A+B=3, \quad -4A-2B=-5.$$

From these equations we find $A=-\frac{1}{2}$, $B=\frac{7}{2}$, and

$$\int\frac{(3x-5)\,dx}{x^2-6x+8}=-\tfrac{1}{2}\int\frac{dx}{x-2}+\frac{7}{2}\int\frac{dx}{x-4},$$

$$=\frac{7}{2}\,\text{l.}\,(x-4)-\tfrac{1}{2}\,\text{l.}\,(x-2)+C.$$

4. As an example of equal simple factors in the denominator, let the differential be

$$\frac{x^2dx}{(x^2-a^2)(x-a)}=\frac{x^2dx}{(x-a)^2(x+a)}.$$

In this case we assume (art. 112),

$$\frac{x^2}{(x-a)^2(x+a)}=\frac{A}{(x-a)^2}+\frac{B}{x-a}+\frac{C}{x+a}$$

$$=\frac{A(x+a)+B(x^2-a^2)+C(x-a)^2}{(x-a)^2(x+a)}$$

$$=\frac{Aa-Ba^2+Ca^2+(A-2aC)x+(B+C)x^2}{(x-a)^2(x+a)}.$$

By equating like terms of the numerators, we have

$$Aa-Ba^2+Ca^2=0, \quad A-2aC=0, \quad B+C=1.$$

Hence, by the ordinary process for resolving simple equations involving three unknown quantities, we find

$$A=\tfrac{1}{2}a, \quad B=\tfrac{3}{4}, \quad C=\tfrac{1}{4},$$

and the transformed differential is

$$\frac{x^2dx}{(x-a)^2(x+a)}=\frac{a}{2}\frac{dx}{(x-a)^2}+\frac{3}{4}\frac{dx}{x-a}+\frac{1}{4}\frac{dx}{x+a}.$$

By integration we have

$$\int\frac{dx}{(x-a)^2}=\frac{-1}{x-a},\int\frac{dx}{x-a}=\text{l.}(x-a),\int\frac{dx}{x+a}=\text{l.}\,(x+a);$$

therefore, supplying the co-efficients of the partial fractions, and, as usual, an indeterminate constant, we have

$$\int\frac{x^2dx}{(x^2-a^2)(x-a)}=-\frac{a}{2}\frac{1}{x-a}+\tfrac{3}{4}\,\text{l.}\,(x-a)$$

$$+\tfrac{1}{4}\,\text{l.}\,(x+a)+const.$$

5. Let the differential be $\frac{x^3+x^2+2}{x(x+1)^2(x-1)^2}dx$.

The denominator contains two pairs of equal factors; we therefore assume (art. 112) $\frac{x^3+x^2+2}{x(x+1)^2(x-1)^2}$ equal to

$$\frac{A}{x}+\frac{B}{(x+1)^2}+\frac{C}{(x+1)}+\frac{D}{(x-1)^2}+\frac{E}{x-1}.$$

By proceeding as in the foregoing examples, uniting the partial fractions into one fraction, and equating the co-efficients of like powers of x, we find

$$A=2, \; B=-\tfrac{1}{2}, \; C=-\tfrac{5}{4}, \; D=1, \; E=-\tfrac{3}{4}.$$

The proposed differential is now decomposed into these,

$$\frac{2dx}{x}-\tfrac{1}{2}\frac{dx}{(x+1)^2}-\tfrac{5}{4}\frac{dx}{x+1}+\frac{dx}{(x-1)^2}-\tfrac{3}{4}\frac{dx}{x-1}.$$

Hence, by integration,

$$\int\frac{x^3+x^2+2}{x(x+1)^2(x-1)^2}dx=2\,\text{l}.\,x+\tfrac{1}{2}\frac{1}{x+1}-\tfrac{5}{4}\,\text{l}.(x+1)$$
$$-\frac{1}{x-1}-\tfrac{3}{4}\,\text{l}.\,(x-1)+\text{const.}$$

6. As an example of a fraction, in which one of the factors in the denominator is a function of the second degree, which does not admit of resolution into real factors of the first degree, let the differential to be integrated be $\frac{a+bx}{x^3-1}dx.$

The denominator $x^3-1=(x-1)\,(x^2+x+1)$. The expression x^2+x+1 is of that kind which cannot be resolved into real factors, although it may into two imaginary factors. For, making $x^2+x+1=0$, and resolving this quadratic equation, we find $x=\frac{-1\pm\sqrt{-3}}{2}$, and $x^2+x+1=(x+\frac{1}{2}+\frac{1}{2}\sqrt{-3})(x+\frac{1}{2}-\frac{1}{2}\sqrt{-3})$.

To avoid impossible quantities, we assume (art. 113),

$$\frac{a+bx}{(x-1)\,(x^2+x-1)}=\frac{A}{x-1}+\frac{Bx+C}{x^2+x-1}.$$

Reducing now the partial fractions to a common denominator, and comparing the co-efficients of like powers, we find

$$A=\tfrac{1}{3}(a\dotplus b),\ B=-\tfrac{1}{3}(a+b),\ C-\tfrac{1}{3}(2a-b).$$

The proposed differential and its equivalent transformed expression will therefore be

$$\frac{a+bx}{(x-1)\,(x^2+x+1)}dx=\frac{a+b}{3}\cdot\frac{dx}{x-1}$$
$$-\tfrac{1}{3}\frac{(a+b)\,x+2a-b}{x^2+x+1}dx.$$

The first integral of these differentials is expressible by a logarithm; to transform the second, we put x^3+x+1 under the form $(x+\frac{1}{2})^2+\frac{3}{4}$, and make $x+\frac{1}{2}=z$; then, $x=z-\frac{1}{2}$, $dx=dz$, $(a+b)\,x+2a-b=(a+b)\,z+\frac{3}{2}(a-b)$, and

$$\tfrac{1}{3}\frac{(a+b)\,x+2a-b}{x^2+x+1}dx=\frac{a+b}{3}\frac{zdz}{z^2+\frac{3}{4}}$$
$$+\frac{a-b}{2}\frac{dz}{z^2+\frac{3}{4}}.$$

The first of these two is also expressible by a logarithm. To simplify the second, we make $z^2=\frac{3}{4}v^2$; so that $dz=\frac{\sqrt{3}}{2}dv$, and $\frac{dz}{z^2+\frac{3}{4}}=\frac{2}{\sqrt{3}}\frac{dv}{1+v^2}$. On the whole, the differential prepared for integration by known rules is

$$\frac{(a+bx)\,dx}{x^3-1}=\frac{a+b}{3}\frac{dx}{x-1}-\frac{a+b}{3}\frac{zdz}{z^2+\frac{3}{4}}$$
$$-\frac{a-b}{\sqrt{3}}\frac{dv}{1+v^3};$$

and, integrating,

$$\int\frac{(a+bx)\,dx}{x^3-1}=\frac{a+b}{3}\,\text{l}.\,(x-1)-\frac{a+b}{6}\,\text{l}.\,(z^2+\tfrac{3}{4})$$
$$-\frac{a-b}{\sqrt{3}}\tan^{-1}v+\text{const.};$$

this integral, by putting for z and v their values in terms of x, will also be

$$\int\frac{(a+bx)\,dx}{x^3-1}=\frac{a+b}{3}\,\text{l}.\,\frac{x-1}{\sqrt{x^2+x+1}}$$
$$-\frac{a-b}{\sqrt{3}}\tan^{-1}\left\{\frac{2x+1}{\sqrt{3}}\right\}+\text{const.}$$

117. The method of resolving a rational fraction into its component partial fractions, by the theory of indeterminate co-efficients (art. 110–113), is the most elementary of any; it is however tedious. We shall therefore now show how the labour may be abridged.

Let $\frac{U}{V}$ be a rational fraction in its lowest terms, the denominator of which has unequal divisors of the first degree; let $x+a$ be one of them, and Q the product of all the other factors, whether of the first or second degree; so that

$$V=(x+a)\,Q.$$

In this case we assume

$$\frac{U}{V}=\frac{A}{x+a}+\frac{P}{Q},$$

where A is independent of x, and P and Q are functions of x, the latter being supposed known. By reducing to a common denominator, and remembering that $V=(x+a)\,Q$, we have the identical equation

$$U=AQ+P\,(x+a),$$

in which, by hypothesis, neither U nor Q are divisible by $x+a$. Let us make $x+a=0$, that is, $x=-a$, and upon that hypothesis let u and q denote the values of U and Q respectively; then the equation becomes $u=Aq$, and hence $A=\frac{u}{q}$. This determines the numerator of the partial fraction $\frac{A}{x+a}$, and in the same way may the numerators of all the partial fractions be found.

As an example, let the fraction to be resolved be

$$\frac{U}{V}=\frac{mx+n}{(x+a)\,(x-b)}=\frac{A}{x+a}+\frac{B}{x-b};$$
$$\text{then, }\frac{mx+n}{x-b}=A+\frac{B}{x-b}(x+a),$$
$$\text{and }\frac{mx+n}{x+a}=B+\frac{A}{x+a}(x-b).$$

Making $x=-a$, the first of these gives

$$A=\frac{-ma+n}{-a-b}=\frac{ma-n}{a+b};$$

and making $x=+b$, the second gives $B=\frac{mb+n}{a+b}$.

Hence we have

$$\frac{mx+n}{(x+a)\,(x-b)}=\frac{1}{a+b}\left\{\frac{ma-n}{x+a}+\frac{mb+n}{x-b}\right\}.$$

118. The differential calculus may be applied to the determination of the constants A, B, &c. Resuming the equation $V=(x+a)\,Q$, we have, by differentiation, $\frac{dV}{dx}=Q+\frac{dQ}{dx}(x+a)$. Suppose that when $x=-a$, then $\frac{dV}{dx}$ becomes v', and, as before, that Q becomes q, the differential equation will now become $v'=q$; and since $A=\frac{u}{q}$, therefore also $A=\frac{u}{v'}$.

In the preceding example, in which $V=(x+a)\,(x-b)$, we have

$$\frac{dV}{dx}=2x+a-b.$$

The supposition that $x=-a$ makes $\frac{dV}{dx}=-a-b=v'$, and the supposition that $x=+b$ makes $\frac{dV}{dx}=a+b=v'$; these values of $v'=q$ give the values of A and B, the same as before.

119. Let us now suppose, that in the fraction $\frac{\text{U}}{\text{V}}$, the denominator $\text{V} = (x+a)^n\,\text{Q}$, that is, the product of n equal factors, and Q, the product of all the remaining factors; so that the assumption is $\frac{\text{U}}{\text{V}} = \frac{\text{U}}{\text{Q}\,(x+a)^n} =$

$$\frac{\text{A}}{(x+a)^n} + \frac{\text{B}}{(x+a)^{n-1}} + \frac{\text{C}}{(x+a)^{n-2}} \ldots + \frac{\text{E}}{x+a} + \frac{\text{P}}{\text{Q}},$$

where A, B, C, ...E are constant quantities, and P, Q functions of x. In this case, multiplying all the terms by $(x+a)^n$, we have

$$\frac{\text{U}}{\text{Q}} = \text{A} + \text{B}\,(x+a) + \text{C}\,(x+a)^2 \ldots$$
$$+ \text{E}\,(x+a)^{n-1} + \frac{\text{P}}{\text{Q}}\,(x+a)^n.$$

The supposition that $x = -a$ gives to U and Q particular values, which, as before, we denote by u and q; the terms which contain $x+a$ all vanish, and we have $\text{A} = \frac{u}{q}$; thus A is known.

Since $\frac{\text{U}-\text{AQ}}{\text{Q}} = \text{B}\,(x+a) + \text{C}\,(x+a)^2 + \&\text{c.}$ the numerator, U — AQ, of the first side of the equation must necessarily be divisible by $x+a$, and may be expressed by $\text{U}_1\,(x+a)$. We have now

$$\frac{\text{U}_1}{\text{Q}} = \text{B} + \text{C}\,(x+a) \ldots + \text{E}\,(x+a)^{n-2} + \frac{\text{P}}{\text{Q}}\,(x+a)^{n-1}.$$

The quantity U_1 not being divisible by $x+a$, the assumption that $x = -a$ will give it a particular value, which we shall denote by u_1. This assumption will give Q the same particular value as before; the terms which contain $(x+a)$ as a factor will all vanish, and we shall have $\text{B} = \frac{u_1}{q}$. In this way may all the remaining numerators C, &c. to E be found.

As a particular example of this process, let the fraction $\frac{\text{U}}{\text{V}}$ be $\frac{x^2}{(1-x)^3\,(1+x^2)}$. We assume

$$\frac{x^2}{(1+x^2)\,(1-x)^3} = \frac{\text{A}}{(1-x)^3} + \frac{\text{B}}{(1-x)^2} + \frac{\text{C}}{1-x} + \frac{\text{P}}{1+x^2};$$

hence, multiplying by $(1-x)^3$, we have

$$\frac{x^2}{1+x^2} = \text{A} + \text{B}\,(1-x) + \text{C}\,(1-x)^2 + \frac{\text{P}}{1+x^2}(1-x)^3.$$

Making $1-x=0$, or $x=1$, we have $\text{A} = \frac{1}{2}$, and $\frac{x^2}{1+x^2} - \text{A} = -\frac{1+x}{2(1+x^2)}(1-x) = \text{B}(1-x) + \text{C}(1-x)^2 + \frac{\text{P}}{1+x^2}(1-x)^3$,

and $-\frac{1+x}{2(1+x^2)} = \text{B} + \text{C}\,(1-x) + \frac{\text{P}}{1+x^2}\,(1-x)^2$;

again, making $x=1$, we find $\text{B} = -\frac{1}{2}$, and

$-\frac{1+x}{2(1+x^2)} - \text{B} = \frac{-x}{2(1+x^2)}\,(1-x) = \text{C}\,(1-x) + \frac{\text{P}}{1+x^2}(1-x)^2$;

$$\text{and } \frac{-x}{2\,(1+x^2)} = \text{C} + \frac{\text{P}}{1+x^2}(1-x).$$

Lastly, making $x = 1$, we have $\text{C} = -\frac{1}{4}$, and the fraction

$$\frac{x^2}{(1+x^2)(1-x)^3} = \tfrac{1}{2}\frac{1}{(1-x)^3} - \tfrac{1}{2}\frac{1}{(1-x)^2} - \tfrac{1}{4}\frac{1}{1-x} + \frac{\text{P}}{1+x^2}.$$

120. In this case we may also find the numerators A, B, C, &c. by the differential calculus. From the equation of art. 119 we have

$$\text{U} = \text{Q}\begin{cases}\text{A} + \text{B}\,(x+a) + \text{C}\,(x+a)^2 \ldots \\ \quad + \text{E}(x+a)^{n-1} + \text{P}(x+a)^n.\end{cases}$$

If we now differentiate this equation $(n-1)$ times in succession, and then make $x+a=0$, both in this equation and those which we deduce from it, there will arise

$$\text{U} = \text{AQ},$$
$$\frac{d\text{U}}{dx} = \text{A}\,\frac{d\text{Q}}{dx} + \text{BQ},$$
$$\frac{d^2\text{U}}{dx^2} = \text{A}\,\frac{d^2\text{Q}}{dx^2} + 2\text{B}\,\frac{d\text{Q}}{dx} + 2\text{CQ},$$
$$\frac{d^3\text{U}}{dx^3} = \text{A}\,\frac{d^3\text{Q}}{dx^3} + 3\text{B}\,\frac{d^2\text{Q}}{dx^2} + 6\text{C}\,\frac{d\text{Q}}{dx} + 6\text{DQ},$$
&c.

equations which determine each of the unknown quantities A, B, C, &c. by means of those which precede it, it being well understood that we substitute after each differentiation $-a$ in the place of x in the differential co-efficients. In this case the most simple way of determining Q will be to divide V by $(x-a)^n$. But it may also be found by differentiation, as in art. 118.

121. Let us now suppose that $\frac{\text{U}}{\text{V}}$, the fraction to be decomposed, has a factor of the second degree, viz. $x^2 + 2\alpha x + \alpha^2 + \beta^2$, which cannot be resolved into two real factors of the first degree.

In this case, $\text{V} = (x^2 + 2\alpha x + \alpha^2 + \beta^2)\,\text{Q}$, and we assume

$$\frac{\text{U}}{\text{V}} = \frac{\text{A}x + \text{B}}{x^2 + 2\alpha x + \alpha^2 + \beta^2} + \frac{\text{P}}{\text{Q}}.$$

Then, $\text{U} = (\text{A}x + \text{B})\,\text{Q} + \text{P}\,(x^2 + 2\alpha x + \alpha^2 + \beta^2)$.

If we substitute for x one of the imaginary roots of the equation $x^2 + 2\alpha x + \alpha^2 + \beta^2 = 0$, the term containing P will disappear, and the result will contain two kinds of terms; one real, and the other imaginary. We must now put the real quantities equal to each other, and also the imaginary quantities; thus two equations will be obtained by which A and B may be determined.

Let the fraction be

$$\frac{x}{(x-1)\,(x^2+x+1)} = \frac{\text{A}x + \text{B}}{x^2+x+1} + \frac{\text{P}}{\text{Q}}.$$

Then $x = (\text{A}x + \text{B})\,(x-1) + \text{P}\,(x^2+x+1)$.

Now $x^2+x+1=0$ gives $x = -\frac{1}{2} \pm \frac{1}{2}\sqrt{-3}$; therefore, by substituting in the last equation, it becomes, after collecting the terms,

$$-\tfrac{1}{2} \pm \tfrac{1}{2}\sqrt{-3} = -\tfrac{3}{2}\text{B} \pm (\tfrac{1}{2}\text{B} - \text{A})\sqrt{-3}.$$

Hence $-\frac{3}{2}\text{B} = -\frac{1}{2}$ and $\frac{1}{2}\text{B} - \text{A} = \frac{1}{2}$, therefore $\text{B} = \frac{1}{3}$ and $\text{A} = -\frac{1}{3}$.

122. In the last place, let us consider the case in which the fraction $\frac{\text{U}}{\text{V}} =$

$$\frac{\text{A}x + \text{B}}{(x^2 + 2\alpha x + \alpha^2 + \beta^2)^n} + \frac{\text{C}x + \text{D}}{(x^2 + 2\alpha x + \alpha^2 + \beta^2)^{n-1}} \ldots\ldots + \frac{\text{P}}{\text{Q}};$$

and here $\text{V} = (x^2 + 2\alpha x + \alpha^2 + \beta^2)^n\,\text{Q}$. We have now

$$\frac{\text{U}}{\text{Q}} = (\text{A}x + \text{B}) + (\text{C}x + \text{D})\,(x^2 + 2\alpha x + \alpha^2\beta^2) \ldots$$
$$+ \frac{\text{P}}{\text{Q}}(x^2 + 2\alpha x + \alpha^2 + \beta^2)^n\text{V}.$$

This case is compounded of the two preceding, and must be treated in the same manner. In the first place, we substitute for x, one of the roots of the equation, $x^2 + 2\alpha x + \alpha^2 + \beta^2 = 0$, by which all the terms containing this quantity disappear, and the equation is reduced to $\frac{V}{Q} = Ax + B$; and here V and Q are functions of the particular value of x, which satisfies the above-mentioned equation. As in the last case, we shall have an equation of the form $r + s\sqrt{-1} = r' + s'\sqrt{-1}$, r and s being composed of constants and the indeterminate quantities A, B; and these last will be found from the equations

$$r = r', \quad s = s'.$$

We now differentiate the preceding equation, and, after omitting the terms in the result that contain $x^2 + 2\alpha x + \alpha^2 + \beta^2$, have

$$\frac{d\left(\frac{V}{Q}\right)}{dx} = A + (2x + 2\alpha)(Cx + D).$$

By substituting in this expression the imaginary value of x, which satisfies the equation $x^2 + 2\alpha x + \alpha^2 + \beta^2 = 0$, and putting the real and imaginary terms on each side equal, two equations will be obtained which determine C and D.

As an example, let the fraction be $\frac{x^3 - 2x^2 + x - 3}{(x^2 - 2x + 2)^2}$. We assume it

$$= \frac{Ax + B}{(x^2 - 2x + 2)^2} + \frac{Cx + D}{x^2 - 2x + 2}.$$

By reducing to a common denominator, we find

$$x^3 - 2x^2 + x - 3 = Ax + B + (Cx + D)(x^2 - 2x + 2),$$

one of the roots of the equation $x^2 - 2x + 2 = 0$ is $x = 1 + \sqrt{-1}$; this being substituted for x, the equation, becomes

$$-4 - \sqrt{-1} = A + B + A\sqrt{-1}.$$

Hence, to determine A and B, we have $A + B = -4$, and $A = -1$; therefore $B = -3$. Substituting the values of A and B, and transposing, we have

$$x^3 - 2x^2 + 2x = (Cx + D)(x^2 - 2x + 2);$$

and, taking the differentials, and dividing by dx,

$$3x^2 - 4x + 2 = (Cx + D)(2x - 2) +, \text{\&c.}$$

By again substituting $1 + \sqrt{-1}$ for x, this equation becomes

$$-2 + 2\sqrt{-1} = -2C + 2(C + D)\sqrt{-1};$$

hence $C = 1$, $D = 0$, and the proposed fraction is equivalent to

$$-\frac{x + 3}{(x^2 - 2x + 2)^2} + \frac{x}{x^2 - 2x + 2}.$$

There is an extensive class of differentials, rational fractions, in which the denominator has the form $x^{2m} \pm 2x^n \cos\alpha + 1$; also of this form, $x^n \pm 1$. How these functions may be resolved into factors of the first and second degrees has been explained in ALGEBRA, art. 274–278. This resolution being effected, the integration may be performed as has been explained.

Integrals of Irrational Fractions.

123. When a differential involves irrational functions, if by any means these can be transformed into others entirely rational, their integration may be effected by the rules already explained.

For example, let the differential be

$$\frac{(1 + \sqrt{x} - \sqrt[3]{x^2})\,dx}{1 + \sqrt[3]{x}}.$$

It is evident, that making $x = z^6$, all the extractions indicated by the radical signs may be effected; and since $dx = 6z^5dz$, the differential is transformed to

$$\frac{6z^5dz(1 + z^3 - z^4)}{1 + z^2};$$

and by actually dividing the numerator by the denominator, this last may be expressed thus,

$$-6(z^7 - z^6 - z^5 + z^4 - z^2 + 1)\,dz - \frac{6dz}{1 + z^2},$$

whose integral is

$$-6\left(\frac{z^8}{8} - \frac{z^7}{7} - \frac{z^6}{6} + \frac{z^5}{5} - \frac{z^3}{3} + z - \tan^{-1} z\right) + \text{const.}$$

By replacing the value of z, viz. $x^{\frac{1}{6}}$, the integral may be expressed in terms of x.

124. We shall now consider those irrational functions which include the radical $\sqrt{a + bx + cx^2}$ only, and which appear under one or other of the two forms,

$$P\,dx\sqrt{a + bx + cx^2}, \quad \frac{P\,dx}{\sqrt{a + bx + cx^2}},$$

where P denotes any rational function of x. These may, however, be included in one; for if the first be multiplied by the radical, and the same quantity written under it as a denominator, it becomes

$$\frac{P(a + bx + cx^2)\,dx}{\sqrt{a + bx + c^2}},$$

an expression of the same kind as the second.

We begin with the simple form, $\frac{dx}{\sqrt{a + bx + cx^2}}$, which, however, has two cases, according as the sign of c in the denominator is positive or negative.

125. I. To integrate the differential $\frac{dx}{\sqrt{a + bx + cx^2}}$.

$$\text{Assume } \sqrt{a + bx + cx^2} = py + \frac{q}{y} \quad\ldots\ldots\ldots\ldots(1)$$

Here p and q are indeterminate constant quantities, to which such values are to be given as shall serve to transform the proposed differential into another that may be a rational fraction; we have now

$$a + bx + cx^2 = p^2y^2 + 2pq + \frac{q^2}{y^2}.$$

To make the left-hand side of this equation a perfect square, we transpose its first term, then multiply both sides by c, and add $\frac{b^2}{4}$ to each side of the result; it then becomes

$$\frac{b^2}{4} + bcx + c^2x^2 = c\left(p^2y^2 + 2pq - a + \frac{b^2}{4c} + \frac{q^2}{y^2}\right).$$

The second side will also become a square if we make

$$2pq - a + \frac{b^2}{4c} = -2pq,$$

$$\text{or } 4pq = \frac{4ac - b^2}{4c},$$

which is evidently always a possible assumption; by this, the equation becomes

$$\frac{b^2}{4} + bcx + c^2x^2 = c\left(p^2y^2 - 2pq + \frac{q^2}{y^2}\right);$$

and hence, by taking the square roots,

$$\frac{b}{2} + cx = \sqrt{c}\left(py - \frac{q}{y}\right) \quad\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(2)$$

From this, by differentiation, we obtain

$$\sqrt{c}\,dx = \frac{dy}{y}\left(py + \frac{q}{y}\right) = \frac{dy}{y}\sqrt{a + bx + cx^2};$$

and hence,

$$\frac{dx}{\sqrt{a + bx + cx^2}} = \frac{1}{\sqrt{c}}\,\frac{dy}{y} \quad\ldots\ldots\ldots\ldots\ldots\ldots\ldots(3)$$

Dividing now both sides of equation (2) by $\sqrt{c}$, and adding the results to equation (1), we get

$$\frac{b}{2\sqrt{c}} + x\sqrt{c} + \sqrt{a+bx+cx^2} = 2py;$$

and, taking the logarithms,

$$\text{l.}\left(\frac{b}{2\sqrt{c}} + x\sqrt{c} + \sqrt{a+bx+cx^2}\right) = \text{l.}\,y + \text{l.}\,(2p) \ldots (4)$$

Now $\text{l.}\,y = \int\frac{dy}{y} + \text{C}$; here, C being any constant whatever, we may suppose it $= \text{C}' - \text{l.}\,(2p)$, where C′ denotes another indeterminate constant; therefore,

$$\text{l.}\,y + \text{l.}\,(2p) = \int\frac{dy}{y} + \text{C}'.$$

By comparing this last equation with (3) and (4), we find

$$\int\frac{dx}{\sqrt{a+bx+cx^2}},$$

$$= \frac{1}{\sqrt{c}}\,\text{l.}\left(\frac{b}{2\sqrt{c}} + x\sqrt{c} + \sqrt{a+bx+cx^2}\right) + \text{C},$$

$$= \frac{1}{\sqrt{c}}\,\text{l.}\left(b + 2cx + 2\sqrt{c}\sqrt{a+bx+cx^2}\right) + \text{C}.$$

These logarithmic functions differ from each other only by the constant l $(2\sqrt{c}.)$

126. II. To integrate the differential $\frac{dx}{\sqrt{a+bx-cx^2}}$, assume $\sqrt{a+bx-cx^2} = p\sin\varphi$ ....(1)
p representing here an indeterminate constant, and φ a variable angle. Then

$$a+bx-cx^2 = p^2\sin^2\varphi = p^2 - p^2\cos^2\varphi;$$

and hence, proceeding as in last article,

$$\frac{b^2}{4} - bcx + c^2x^2 = cp^2\cos^2\varphi + \frac{b^2}{4} + ac - p^2c.$$

The left-hand side of the equation is now a complete square, and to make the right also a square, we assume that

$$cp^2 = \frac{b^2}{4} + ac, \text{ or } p\sqrt{c} = \frac{\sqrt{b^2+4ac}}{2} \ldots\ldots\ldots (2)$$

and thus obtain

$$\frac{b^2}{4} - bcx + c^2x^2 = cp^2\cos^2\varphi,$$

and, taking the square roots,

$$\frac{b}{2} - cx = \sqrt{c}\,p\cos\varphi \ldots\ldots\ldots\ldots\ldots (3)$$

and hence, differentiating, and dividing by $\sqrt{c}$,

$$dx = \frac{d\varphi}{\sqrt{c}}p\sin\varphi = \frac{d\varphi}{\sqrt{c}}\sqrt{a+bx-cx^2};$$

and hence,

$$\frac{dx}{\sqrt{a+bx-cx^2}} = \frac{1}{\sqrt{c}}\,d\varphi.$$

Taking now the integral, we have

$$\int\frac{dx}{\sqrt{a+bx-cx^2}} = \frac{1}{\sqrt{c}}\varphi + \text{const.}$$

To determine φ, we have, (3) and (2),

$$\cos\varphi = \frac{b-2cx}{2\sqrt{c}\,p} = \frac{b-2cx}{\sqrt{b^2+4ac}}.$$

Therefore,

$$\int\frac{dx}{\sqrt{a+bx-cx^2}} = \frac{1}{\sqrt{c}}\cos^{-1}\frac{b-2cx}{\sqrt{b^2+4ac}} + \text{C}.$$

We have also

$$\int\frac{dx}{\sqrt{a+bx-cx^2}} = \frac{1}{\sqrt{c}}\sin^{-1}\frac{2cx-b}{\sqrt{b^2+4ac}} + \text{C};$$

for the angle whose cosine is any number v differs from the angle whose sine is $-v$ by a right angle, which is a constant, and therefore the differentials of these angles will be the same expression.

127. We shall now integrate the formula

$$\frac{x^n dx}{\sqrt{a+bx+cx^2}},$$

n being any whole number. We put

$$\text{X} = \sqrt{a+bx+cx^2},\quad y = x^m\sqrt{a+bx+cx^2} = x^m\text{X},$$

$$\text{then } y^2 = ax^{2m} + bx^{2m+1} + cx^{2m+2},$$

and differentiating, we have $2ydy =$

$$(2max^{2m-1} + (2m+1)bx^{2m} + (2m+2)cx^{2m+1})dx;$$

and hence, dividing by $y = x^m\text{X}$,

$$2dy = 2ma\frac{x^{m-1}dx}{\text{X}} + (2m+1)b\frac{x^m dx}{\text{X}}$$

$$+ (2m+2)c\frac{x^{m+1}dx}{\text{X}}.$$

Let us now make $m+1 = n$, and therefore $m = n-1$, $m-1 = n-2$, $2m = 2n-2$, $2m+1 = 2n-1$, $2m+2 = 2n$; thus we obtain

$$2dy = (2n-2)a\frac{x^{n-2}dx}{\text{X}} + (2n-1)b\frac{x^{n-1}dx}{\text{X}}$$

$$+ 2nc\frac{x^n dx}{\text{X}};$$

and hence, by proper arrangement of the terms,

$$\frac{x^n ax}{\text{X}} = \frac{dy}{nc} - \frac{2n-1}{2n}\cdot\frac{b}{c}\cdot\frac{x^{n-1}dx}{\text{X}} - \frac{n-1}{n}\cdot\frac{a}{c}\cdot\frac{x^{n-2}dx}{\text{X}};$$

and, by integration, and putting for y and X the functions they represent, we have

$$\int\frac{x^n dx}{\sqrt{a+bx+cx^2}} = \frac{1}{nc}x^{n-1}\sqrt{a+bx+cx^2}$$

$$- \frac{2n-1}{2n}\cdot\frac{b}{c}\int\frac{x^{n-1}dx}{\sqrt{a+bx+cx^2}}$$

$$- \frac{n-1}{n}\cdot\frac{a}{c}\int\frac{x^{n-2}dx}{\sqrt{a+bx+cx^2}}.$$

The proposed integral is now expressed by an algebraic function, and two other integrals of the same form, but in which the exponents of x are of lower degrees. We have found its value (art. 125, 126) when $n = 0$, a case to which the formula just found does not apply, because then, n entering into the denominators of the fractions, they become infinite. When $n = 1$, the last of the two integrals in the second side of the equation vanishes, because its coefficient $= 0$, and we have

$$\int\frac{xdx}{\sqrt{a+bx+cx^2}} = \frac{1}{c}\sqrt{a+bx+cx^2}$$

$$- \frac{b}{2c}\int\frac{dx}{\sqrt{a+bx+cx^2}}.$$

Knowing now the integrals in the cases of $n = 0$ and $n = 1$, the preceding general formula gives it in the case of $n = 2$; and in the case of $n = 3$, it is found from the cases of $n = 1$ and $n = 2$; and so on to any extent, supposing n to be a positive number.

128. When n is negative, the formula will be better under another form. Writing $-n$ instead of $+n$, and arranging the terms of the result anew, we have

$$\int\frac{dx}{x\sqrt{}^{n}\overline{a+bx+cx^2}}=\frac{-1}{(n-1)a}\,\frac{\sqrt{a+bx+cx^2}}{x^{n-1}}$$
$$-\frac{2n-3}{2n-2}\cdot\frac{b}{a}\int\frac{dx}{x^{n-1}\sqrt{a+bx+cx^2}}$$
$$-\frac{n-2}{n-1}\cdot\frac{c}{a}\int\frac{dx}{x^{n-2}\sqrt{a+bx+cx^2}}.$$

In this formula, n is understood to be positive.

129. This formula of transformation will not apply to the case of $n=1$, because then the fractions which have $n-1$ in the denominator become infinite. It is therefore necessary to investigate the integral of $\frac{dx}{x\sqrt{a+bx+cx^2}}$ separately. Let $x=\frac{1}{y}$; then $\frac{dx}{x}=\frac{-dy}{y}$, and

$$\frac{dx}{x\sqrt{a+bx+cx^2}}=\frac{-dy}{\sqrt{c+by+ay^2}}.$$

This transformed differential has two cases, according as a is positive or negative; when a is positive, the integral is, by article 125,

$$-\frac{1}{\sqrt{a}}\,\mathrm{l.}\,(b+2ay+2\sqrt{a}\,\sqrt{c+by+ay^2})+\mathrm{C}.$$

We are at liberty to give the radical $\sqrt{a}$ either the sign $+$ or the sign $-$; therefore, giving it the latter, the integral is

$$\frac{1}{\sqrt{a}}\,\mathrm{l.}\,(b+2ay-2\sqrt{a}\,\sqrt{c+by+ay^2})+\mathrm{C};$$

and hence, substituting for y its equivalent $\frac{1}{x}$, we have

$$\int\frac{dx}{x\sqrt{a+bx+cx^2}}$$
$$=\frac{1}{\sqrt{a}}\,\mathrm{l.}\,\frac{2a+bx-2\sqrt{a}\,\sqrt{a+bx+cx^2}}{x}+\mathrm{C};$$

observing, as above stated, that the radical $\sqrt{a}$ may have the sign $+$ and also the sign $-$.

In the second case we have

$$\frac{dx}{x\sqrt{-a+bx+cx^2}}=\frac{-dy}{\sqrt{c+by-ay^2}}.$$

Now, by art. 126,

$$\int\frac{-dy}{\sqrt{c+by-a^2y^2}}=-\frac{1}{\sqrt{a}}\sin^{-1}\frac{2ay-b}{\sqrt{b^2+4ac}}+\mathrm{C}$$
$$=\frac{1}{\sqrt{a}}\cos^{-1}\frac{2ay-b}{\sqrt{b^2+4ac}}+\mathrm{C}.$$

Therefore, putting $\frac{1}{x}$ instead of y,

$$\int\frac{dx}{x\sqrt{-a+bx+cx^2}}=\frac{1}{\sqrt{a}}\cos^{-1}\frac{2a-bx}{x\sqrt{b^2+4ac}}+\mathrm{C}.$$

130. The formulæ investigated from articles 125 to 128 serve for the integration of innumerable differentials. Thus, from art. 125 we have

$$\int\frac{dx}{\sqrt{a+x^2}}=\mathrm{l.}\,(x+\sqrt{a+x^2})+\mathrm{C}$$
$$\int\frac{dx}{\sqrt{bx+x^2}}=\mathrm{l.}\,(\tfrac{1}{2}b+x+\sqrt{bx+x^2})+\mathrm{C};$$

and, from the first formula of art. 129,

$$\int\frac{adx}{x\sqrt{a^2+cx^2}}=\mathrm{l.}\,\frac{2a^2-2a\sqrt{a^2+cx^2}}{x}+\mathrm{C}$$
$$=\mathrm{l.}\,\frac{a-\sqrt{a^2+cx^2}}{x}+\mathrm{C}.$$

The second of these integrals is obtained from the first by passing l. $(2a)$ into the arbitrary constant C. It may yet have another form; for

$$\int\frac{2adx}{x\sqrt{a^2+cx^2}}=\mathrm{l.}\,\frac{(a-\sqrt{a^2+cx^2})}{-cx^2}+\mathrm{C}.$$

Now $-cx^2=(a+\sqrt{a^2+cx^2})\,(a-\sqrt{a^2+cx^2})$; therefore, substituting and reducing,

$$\int\frac{adx}{x\sqrt{a^2+cx^2}}=\tfrac{1}{2}\,\mathrm{l.}\,\frac{a-\sqrt{a^2+cx^2}}{a+\sqrt{a^2+cx^2}}+\mathrm{C}.$$

This example shows that the integral is much modified by the arbitrary constant which enters it.

131. Corresponding to these logarithmic integrals there is a set of similar integrals which are expressed by angles or arcs of a circle. Thus we have, art. 126,

$$\int\frac{dx}{\sqrt{a^2-x^2}}=\sin^{-1}\frac{x}{a}+\mathrm{C},$$
$$\int\frac{dx}{\sqrt{ax-x^2}}=\cos^{-1}\left(1-2\frac{x}{a}\right)+\mathrm{C},$$

and by formula 2 of art. 129,

$$\frac{adx}{x\sqrt{x^2-a^2}}=\sec^{-1}\frac{x}{a}+\mathrm{C}=\cos^{-1}\frac{a}{x}+\mathrm{C}.$$

132. As an example of the way of proceeding in the integration of a differential which involves radical quantities, let it be proposed to integrate the differential

$$\frac{dx}{x}\sqrt{\frac{a^2-x^2}{x^2-b^2}}.$$

By an obvious transformation, we find

$$\frac{dx}{x}\sqrt{\frac{a^2-x^2}{x^2-b^2}}=\frac{a^2dx}{x\sqrt{\{(a^2-x^2)(x^2-b^2)\}}}$$
$$-\frac{xdx}{\{\sqrt{(a^2-x^2)(x^2-b^2)}\}}.$$

The first of these differentials may be otherwise expressed thus,

$$-\frac{a}{b}\,\frac{\frac{1}{x}\,d\left(\frac{1}{x}\right)}{\sqrt{\left\{\left(\frac{1}{a^2}-\frac{1}{x^2}\right)\left(\frac{1}{x^2}-\frac{1}{b^2}\right)\right\}}}.$$

Therefore we have

$$\frac{dx}{x}\sqrt{\frac{a^2-x^2}{x^2-b^2}}=\frac{-xdx}{\sqrt{\{(a^2-x^2)(x^2-b^2)\}}}$$
$$-\frac{a}{b}\,\frac{\frac{1}{x}\,d\left(\frac{1}{x}\right)}{\sqrt{\left\{\left(\frac{1}{a^2}-\frac{1}{x^2}\right)\left(\frac{1}{x^2}-\frac{1}{b^2}\right)\right\}}},$$

and it is evident that the two differentials have precisely the same form.

To integrate the first of these, let us assume

$$x^2=a^2\cos^2\varphi+b^2\sin^2\varphi;$$
$$\text{then } xdx=(b^2-a^2)\sin\varphi\cos\varphi\,d\varphi,$$
$$a^2-x^2=(b^2-a^2)\sin^2\varphi\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(1)$$
$$x^2-b^2=(b^2-a^2)\cos^2\varphi\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(2)$$
$$\frac{-xdx}{\sqrt{\{(a^2-x^2)(x^2-b^2)\}}}=\frac{(a^2-b^2)\cos\varphi\sin\varphi d\varphi}{(a-b^2)\cos\varphi\sin\varphi}=d\varphi.$$

Exactly in the same way, if we make

$$\frac{1}{x^2}=\frac{1}{a^2}\cos^2\psi+\frac{1}{b^2}\sin^2\psi,$$

Inverse Method.

we get

$$\frac{1}{x}d\left(\frac{1}{x}\right)=\left(\frac{1}{b^2}-\frac{1}{a^2}\right)\sin\psi\cos\psi d\psi,$$

$$\frac{1}{a^2}-\frac{1}{x^2}=\left(\frac{1}{a^2}-\frac{1}{b^2}\right)\sin^2\psi\ldots\ldots\ldots\ldots\ldots\ldots(3)$$

$$\frac{1}{x^2}-\frac{1}{b^2}=\left(\frac{1}{a^2}-\frac{1}{b^2}\right)\cos^2\psi\ldots\ldots\ldots\ldots\ldots\ldots(4)$$

$$\frac{-\frac{1}{x}d\left(\frac{1}{x}\right)}{\sqrt{\left\{\left(\frac{1}{a^2}-\frac{1}{x^2}\right)\left(\frac{1}{x^2}-\frac{1}{b^2}\right)\right\}}}=\frac{\left(\frac{1}{b^2}-\frac{1}{a^2}\right)\sin\psi\cos\psi d\psi}{\left(\frac{1}{b^2}-\frac{1}{a^2}\right)\sin\psi\cos\psi}=d\psi.$$

On the whole, if φ and ψ be such angles that

$$\cos\varphi=\sqrt{\frac{x^2-b^2}{a^2-b^2}},\quad \cos\psi=\frac{a}{x}\cos\varphi;$$

then

$$\int\frac{dx}{x}\sqrt{\frac{a^2-x^2}{x^2-b^2}}=\varphi+\psi+\text{const.}$$

Integration of Binomial Differentials.

133. These differentials are represented by the formula

$$x^{m-1}dx\,(a+bx^n)^{\frac{q}{p}},$$

whose generality will not be affected by supposing that m and n are whole numbers. The object we propose is to find in what case this differential may be made rational.

We assume $a+bx^n=z^q$, so that $(a+bx^n)^{\frac{p}{q}}=z^p$; we then find

$$x^n=\frac{z^q-a}{b},\quad x^m=\left(\frac{z^q-a}{b}\right)^{\frac{m}{n}},$$

$$x^{m-1}dx=\frac{q}{nb}z^{q-1}\left(\frac{z^q-a}{b}\right)^{\frac{m}{n}-1};$$

and the proposed differential is now transformed into

$$\frac{q}{nb}z^{p+q-1}\,dz\left(\frac{z^q-a}{b}\right)^{\frac{m}{n}-1},$$

an expression which is evidently rational whenever $\frac{m}{n}$ is a whole number.

The differential $x^8dx\,(a+bx^3)^{\frac{p}{q}}$ satisfies this condition, since $m=9$, $n=3$, $\frac{m}{n}=3$, and it is transformed into

$$\frac{q}{3b}z^{p+q-1}\,dz\left(\frac{z^q-a}{b}\right)^2.$$

The differential $x^{m-1}\,dx\,(a+bx^n)^{\frac{p}{q}}$ admits of another form, by making the index of x between the brackets negative, or by dividing the quantity $a+bx^n$ by x^n; then we have

$$x^{m-1}dx\,(a+bx^n)^{\frac{p}{q}}=x^{m-1}\,dx\left\{(ax^{-n}+b)\,x^n\right\}^{\frac{p}{q}}$$

$$=x^{m+\frac{np}{q}-1}\,dx\,(ax^{-n}+b)^{\frac{p}{q}};$$

and by the process preceding, the last of these expressions may be made rational, whenever $\frac{m+\frac{np}{q}}{n}$ is a whole number; or, what is the same thing, whenever $\frac{m}{n}+\frac{p}{q}$ is an integer.

The differential $x^4\,dx\,(a+bx^3)^{\frac{1}{3}}$ is of this description, since $\frac{m}{n}=\frac{5}{3}$, $\frac{p}{q}=\frac{1}{3}$, $\frac{m}{n}+\frac{p}{q}=\frac{6}{3}=2$.

In applying to the differential

$$x^{m+\frac{np}{q}-1}\,dx\,(ax^{-n}+b)^{\frac{p}{q}},$$

the substitution indicated for the first form of this differential, we shall make $ax^{-n}+b=z^q$, and thence deduce $a+bx^n=x^n\,z^q$; and if we transform immediately the expression $x^{m-1}\,dx\,(a+bx^n)^{\frac{p}{q}}$ by means of the equation preceding, we shall evidently obtain the same result as if we had at first given it the form

$$x^{m+\frac{np}{q}-1}\,dx(ax^{-n}+b)^{\frac{p}{q}}.$$

134. Since it is not possible to integrate in every case the formula $x^{m-1}\,dx\,(a+bx^n)^{\frac{p}{q}}$, we may try to change it into another more simple, as has been done in integrating a differential (art. 115). We have found that $\int udv=uv-\int vdu$. If therefore we can decompose the differential into two factors, one of which being integrable, may be represented by dv, and the other by u, the integration of the proposed differential will be made to depend on that of vdu, which in some cases will be more simple than the proposed differential. This method, which is at once extensive and elegant, is called *integration by parts.*

For the sake of abridging, we shall write simply p instead of $\frac{p}{q}$, supposing p to represent a fractional number. The formula will then become

$$x^{m-1}\,dx\,(a+bx^n\ ^p.$$

Among the different ways of resolving this differential into factors, we choose this:

$$x^{m-n}\,x^{n-1}\,dx\,(a+bx^n)^p.$$

One of the factors, $x^{n-1}\,dx\,(a+bx^n)^p$, is integrable, whatever be the value of p (art. 108); representing it therefore by dv, we have

$$v=\frac{(a+bx\ )^{p+1}}{nb\,(p+1)},\text{ and }u=x^{m-n},$$

whence there results

$$\int x^{m-1}dx\,(a+bx^n)^p=\frac{x^{m-n}(a+bx^n)^{p+1}}{nb\,(p+1)},$$

$$-\frac{m-n}{nb\,(p+1)}\int x^{m-n-1}\,dx\,(a+bx^n)^{p+1};$$

but $\int x^{m-n-1}\,dx\,(a+bx^n)^{p+1}$

$$=\int x^{m-n-1}\,dx\,(a+bx^n)^p\,(a+bx^n)=$$

$$a\int x^{m-n-1}\,dx\,(a+bx)^p+$$

$$b\int x^{m-1}\,dx\,(a+bx^n)^p,$$

Inverse Method.

putting this last in the preceding equation; and collecting the terms containing the integral $\int x^{m-1}dx(a+bx^n)^p$, we obtain, after reduction,

(A.)

$$\int x^{m-1}dx\,(a+bx^n)^p = \frac{x^{m-n}(a+bx^n)^{p+1}}{b\,(pn+m)}$$

$$-\frac{a\,(m-n)}{b\,(pn+m)}\cdot\int x^{m-n-1}dx\,(a+bx^n)^p.$$

It is obvious that since we may reduce the integration of $x^{m-1}dx\,(a+bx^n)^p$ to that of $x^{m-n-1}dx\,(a+bx^n)^p$, we may reduce this last to the integration of $x^{m-2n-1}dx\,(a+bx^n)^p$ by writing $m-n$ in the place of m in equation (A); then, by changing $m-n$ into $m-2n$, we shall be able to determine $\int x^{m-2n-1}dx\,(a+bx^n)^p$ by means of $\int x^{m-3n-1}dx\,(a+bx^n)^p$, and so on.

In general, if r denote the number of reductions, we shall at last come to $\int x^{m-rn-1}dx\,(a+bx^n)^p$, and the last formula will be

$$\int x^{m-(r-1)n-1}dx\,(a+bx^n)^p$$

$$=\frac{x^{m-rn}(a+bx^n)^{p+1}}{b\{pn+m-(r-1)n\}}-$$

$$\frac{a\,(m-rn)}{b\{pn+m-(r-1)n\}}\int x^{m-rn-1}dx\,(a+bx^n)^p.$$

It appears from this formula, that if m be a multiple of n, the integration of the proposed formula $x^{m-1}dx\,(a+bx^n)^p$ may be effected in algebraic terms, since the last integral of the transformed expression will be multiplied by $m-rn=0$. This result agrees with that of art. 133.

135. There is another way of reduction by which the exponent of the quantity within the parenthesis may be diminished by an unit; for this purpose it is only necessary to observe that

$$\int x^{m-1}dx(a+bx^n)^p$$

$$\int x^{m-1}dx(a+bx^n)^{p-1}(a+bx^n)$$

$$=a\int x^{m-1}dx(a+bx^n)^{p-1}$$

$$+\,b\int x^{m+n-1}dx(a+bx^n)^{p-1}.$$

Formula (A), by changing m into $m+n$, and p into $p-1$, gives

$$\int x^{m+n-1}dx(a+bx^n)^{p-1}=$$

$$\frac{x^m(a+bx^n)^p-am\int x^{m-1}dx(a+bx^n)^{p-1}}{b(pn+m)}.$$

Substituting this value in the preceding equation, we have

(B)

$$\int x^{m-1}dx(a+bx^n)^p=\frac{x^m(a+bx^n)^p}{pn+m}$$

$$+\frac{pna}{pn+m}\int x^{m-1}dx(a+bx^n)^{p-1}.$$

By this formula we may take away successively from p as many units as it contains; and by its application, along with formula (A), we may make the integral

$$\int x^{m-1}dx(a+bx^n)^p \text{ depend on}$$

$\int x^{m-rn-1}dx(a+bx^n)^{p-s}$, rn being the greatest multiple of m contained in $m-1$, and s the greatest whole number contained in p.

The integral $\int x^7dx(a+bx^3)^{\frac{5}{2}}$, for example, may be reduced by formula (A) successively to

$$\int x^4dx(a+bx^3)^{\frac{5}{2}},\ \int xdx(a+bx^3)^{\frac{5}{2}};$$

and by formula (B), $\int xdx(a+bx^3)^{\frac{5}{2}}$ is reduced to

$\int xdx(a+bx^3)^{\frac{3}{2}}$, and that again to $\int xdx(a+bx^3)^{\frac{1}{2}}$.

136. It is evident that if m and n were negative, the formulæ (A) and (B) would not accomplish the purpose for which they have been investigated; they would then increase the exponent of x without the parenthesis, as well as that of the parenthesis itself; but by reversing them we shall find others suited to the case in question. From formula (A) we deduce

$$\int x^{m-n-1}dx(a+bx^n)^p=\frac{x^{m-n}(a+bx^n)^{p+1}}{a(m-n)},$$

$$-\frac{b(m+np)}{a(m-n)}\int x^{m-1}dx(a+bx^n)^p.$$

In this expression, substitute $m+n$ in place of n, and it becomes

(C)

$$\int x^{m-1}dx(a+bx^n)^p=\frac{x^m(a+bx^n)^{p+1}}{am}$$

$$-\frac{b(m+n+np)}{am}\int x^{m+n-1}dx(a+bx^n)^p.$$

This formula diminishes the exponent without the parenthesis, since $m+n-1$ becomes $-m+n-1$ when $-m$ is put instead of $+m$.

To reverse the formula (B), we take

$$\int x^{m-1}dx(a+bx^n)^{p-1}=-\frac{x^m(a+bx^n)^p}{pna}$$

$$-\frac{m+np}{pna}\int x^{m-1}dx(a+bx^n)^p;$$

then we write $p+1$ instead of p, and thus find formula

(D)

$$\int x^{m-1}dx(a+bx^n)^p=-\frac{x^m(a+bx^n)^{p+1}}{na(p+1)}$$

$$-\frac{m+n+np}{na(p+1)}\int x^{m-1}dx(a+bx^n)^{p+1}.$$

This formula answers the proposed purpose, since $p+1$ becomes $-p+1$, when p is negative.

137. Let the formula be $\int\frac{x^{m-1}dx}{\sqrt{1-x^2}}$, where m is a whole positive number. Making $a=1$, $b=-1$, $n=2$, $p=-\frac{1}{2}$, we find

$$\int\frac{x^{m-1}dx}{\sqrt{1-x^2}}=-\frac{x^{m-2}\sqrt{1-x^2}}{m-1}+\frac{m-2}{m-1}\int\frac{x^{m-3}dx}{\sqrt{1-x^2}}.$$

Inverse Method.

Writing m in place of $m - 1$, we have

$$\int \frac{x^m dx}{\sqrt{1-x^2}} = -\frac{x^{m-1}\sqrt{1-x^2}}{m} + \frac{m-1}{m}\int \frac{x^{m-2}dx}{\sqrt{1-x^2}}.$$

If we give to m successive different values, beginning with the uneven numbers, we have

$$\int \frac{xdx}{\sqrt{1-x^2}} = -\sqrt{1-x^2} + \text{const.}$$

$$\int \frac{x^3dx}{\sqrt{1-x^2}} = -\tfrac{1}{3}x^2\sqrt{1-x^2} + \tfrac{2}{3}\int \frac{xdx}{\sqrt{1-x^2}},$$

$$\int \frac{x^5dx}{\sqrt{1-x^2}} = -\tfrac{1}{5}x^4\sqrt{1-x^2} + \tfrac{4}{5}\int \frac{x^3dx}{\sqrt{1-x^2}},$$

$$\int \frac{x^7dx}{\sqrt{1-x^2}} = \tfrac{1}{7}x^6\sqrt{1-x^2} + \tfrac{6}{7}\,\frac{x^5dx}{\sqrt{1-x^2}},$$

&c.

and hence we deduce

$$\int \frac{x^3dx}{\sqrt{1-x^2}} = -\left(\tfrac{1}{3}x^2 + \frac{1.2}{1.3}\right)\sqrt{1-x^2},$$

$$\int \frac{x^5dx}{\sqrt{1-x^2}} = -\left(\tfrac{1}{5}x^4 + \frac{1.4}{3.5}x^2 + \frac{1.2.4}{1.3.5}\right)\sqrt{1-x^2},$$

$$\int \frac{x^7dx}{\sqrt{1-x^2}} = -\left(\tfrac{1}{7}x^6 + \frac{1.6}{5.7}x^4 + \frac{1.4.6}{3.5.7}x^2 \right.$$
$$\left. + \frac{1.2.4.6}{1.3.5.7}\right)\sqrt{1-x^2},$$

&c.

The law of formation of the integrals is evident; an arbitrary constant is to be annexed to each.

Let us now consider the even values of m. Supposing $m = 2, 4, 6$, &c. we have

$$\int \frac{x^2dx}{\sqrt{1-x^2}} = -\tfrac{1}{2}x\sqrt{1-x^2} + \tfrac{1}{2}\int \frac{dx}{\sqrt{1-x^2}},$$

$$\int \frac{x^4dx}{\sqrt{1-x^4}} = -\tfrac{1}{4}x^3\sqrt{1-x^2} + \tfrac{3}{4}\int \frac{x^2dx}{\sqrt{1-x^2}},$$

$$\int \frac{x^6dx}{\sqrt{1-x^2}} = -\tfrac{1}{6}x^5\sqrt{1-x^2} + \tfrac{5}{6}\int \frac{x^4dx}{\sqrt{1-x^2}}.$$

&c.

Here all the integrals depend on

$$\int \frac{dx}{\sqrt{1-x^2}} = \sin^{-1} x + \text{const. (art. 23.)}$$

Let us call A the arc whose sine is x, and we have

$$\int \frac{dx}{\sqrt{1-x^2}} = \text{A} + \text{const.}$$

$$\int \frac{x^2dx}{\sqrt{1-x^2}} = -\tfrac{1}{2}x\sqrt{1-x^2} + \tfrac{1}{2}\text{A} + \text{const.}$$

$$\int \frac{x^4dx}{\sqrt{1-x^2}} = -\left(\tfrac{1}{4}x^5 + \frac{1.3}{2.4}x\right)\sqrt{1-x^3}$$
$$+ \frac{1.3}{2.4}\text{A} + \text{const.}$$

$$\int \frac{x^6dx}{\sqrt{1-x^2}} = -\left(\tfrac{1}{6}x^5 + \frac{1.5}{4.6}x^3 + \frac{1.3.5}{2.4.6}x\right)\sqrt{1-x^2}$$
$$+ \frac{1.3.5}{2.4.6}\text{A} + \text{const.}$$

138. Let us now consider the formulæ which answer to the case of m negative; then by formula (C) art. 136,

$$\int \frac{x^{-m-1}dx}{\sqrt{1-x^2}} = -\frac{x^{-m}\sqrt{1-x^2}}{m}$$
$$+ \frac{m-1}{m}\int \frac{x^{-m+1}dx}{\sqrt{1-x^2}}.$$

Writing $-m$ instead of $-m-1$, this becomes

$$\int \frac{dx}{x^m\sqrt{1-x^2}} = \frac{-\sqrt{1-x^2}}{(m-1)x^{m-1}}$$
$$+ \frac{m-2}{m-1}\int \frac{dx}{x^{m-2}\sqrt{1-x^2}}.$$

We cannot make $m = 1$, because that value would make the denominator *zero* and the co-efficient infinite. We have already found the integral in this case, viz.

$$\int \frac{dx}{x\sqrt{1-x^2}} = -\text{l.}\,\frac{1+\sqrt{1-x^2}}{x} + \text{const. (art. 130).}$$

Proceeding now, making $m = 3$, $m = 5$, &c. we have

$$\int \frac{dx}{x^3\sqrt{1-x^2}} = -\frac{\sqrt{1-x^2}}{2x^2} + \tfrac{1}{2}\int \frac{dx}{x\sqrt{1-x^2}},$$

$$\int \frac{dx}{x^5\sqrt{1-x^2}} = -\frac{\sqrt{1-x^2}}{4x^4} + \tfrac{3}{4}\int \frac{dx}{x^3\sqrt{1-x^2}},$$

$$\int \frac{d}{x^7\sqrt{1-x^2}} = -\frac{\sqrt{1-x^2}}{6x^6} + \tfrac{5}{6}\int \frac{dx}{x^5\sqrt{1-x^2}}.$$

&c.

Making $m = 2$, $m = 4$, $m = 6$, &c. we find

$$\int \frac{dx}{x^2\sqrt{1-x^2}} = -\frac{\sqrt{1-x^2}}{x} + \text{const.}$$

$$\frac{dx}{x^4\sqrt{1-x^4}} = -\frac{\sqrt{1-x^2}}{3x^3} + \tfrac{2}{3}\int \frac{dx}{x^2\sqrt{1-x^2}},$$

$$\frac{dx}{x^6\sqrt{1-x^6}} = -\frac{\sqrt{1-x^2}}{5x^5} + \tfrac{4}{5}\int \frac{dx}{x^4\sqrt{1-x^2}},$$

&c.

From these two series of equations we deduce, as in the former article, a series of differentials integrated by logarithms, and another by algebraic formulæ.

Integration by Series.

139. The integral $\int \text{X}\,dx$ is easily found when the function X is expanded into a series, because then we have only to integrate a series of single terms in succession, to which the rule of art. 104 immediately applies.

Thus, let $\text{X} = \text{A}x^m + \text{B}x^{m+n} + \text{C}x^{m+2n} + \text{D}x^{m+3n} +$ &c. If both members of this equation be multiplied by dx, and each term be separately integrated, we have

$$\int \text{X}\,dx = \frac{\text{A}x^{m+1}}{m+1} + \frac{\text{B}x^{m+n+1}}{m+n+1} + \frac{\text{C}x^{m+2n+1}}{m+2n+1} + \text{\&c.} + c.$$

If in the expansion of X any term of the form $\frac{\text{E}}{x}$ occur, the integral corresponding to that term will be E l. x (art. 20). We shall now give particular examples.

Ex. 1. To integrate $\frac{dx}{a+x}$ by a series.

We know that the integral comprehends in it Napier's logarithm of $a + x$ (art. 20). Now, by division,

$$\frac{1}{a+x} = \frac{1}{a} - \frac{x}{a^2} + \frac{x^2}{a^3} - \frac{x^3}{a^4} + \frac{x^5}{a^6} - \text{\&c.}$$

Therefore, multiplying by dx, and integrating,

$$\int \frac{dx}{a+x} = \frac{x}{a} - \frac{x^2}{2a^2} + \frac{x^3}{3a^3} - \frac{x^4}{4a^4} + \text{\&c.} + \text{C}.$$

This series expresses the general integral, without any regard to its particular application. If, however, we consider it as expressing l. $(a + x)$, then we have

$$\text{l.}\,(a+x)=\frac{x}{a}-\frac{x^2}{2a^2}+\frac{x^3}{3a^3}-\frac{x^4}{4a^4}+\&c.+C.$$

The constant quantity C is now no longer indeterminate; it must have such a value as satisfies this equation whatever be the value of x. If we make $x=0$, then all the terms of the series vanish, and we have $\text{l.}\,a=C$.

Thus the value of C is determined, and we have

$$\text{l.}\,(a+x)=\text{l.}\,a+\frac{x}{a}-\frac{x^2}{2a^2}+\frac{x^3}{3a^3}-\&c.$$

This result agrees with what we found (art. 86).

Ex. 2. To integrate $\frac{dx}{1+x^2}$ by a series. By division,

$$\frac{1}{1+x^2}=1-x^2+x^4-x^6+\&c.$$

Multiplying now both sides of this equation by dx, and integrating, we have

$$\int\frac{dx}{1+x^2}=x-\frac{x^3}{3}+\frac{x^5}{5}-\frac{x^7}{7}+\&c.+C.$$

As a formula purely analytical, the constant C must be regarded as indeterminate. We know, however, that $\frac{dx}{1+x^2}$ is the integral of an arc of which x is the tangent, the radius being unity (art. 22, Ex. 3). Therefore, if we mean to express $\tan^{-1}x$ by a series, then

$$\tan^{-1}x=x-\frac{x^3}{3}+\frac{x^5}{5}-\frac{x^7}{7}+\&c.+C.$$

The constant C has now a precise value, and it may be found by giving any corresponding known values to $\tan-x$ and x. Now we know that when $\tan^{-1}x=0$, then $x=0$. Therefore, considering that when all the terms in the series vanish, we have $0=0+C$; thus it appears that $C=0$.

Ex. 3. In the last example, the integral of $\frac{dx}{1+x^2}$ was expressed by a series of terms formed from the ascending powers of x. We may, however, express that integral by a descending series. By division

$$\frac{1}{x^2+1}=\frac{1}{x^2}-\frac{1}{x^4}+\frac{1}{x^6}-\&c.$$

$$\text{And}\int\frac{dx}{x^2+1}=-\frac{1}{x}+\frac{1}{3x^3}-\frac{1}{5x^5}+\&c.+C.$$

If we now regard the integral as the angle or arc whose tangent is x, we have

$$\tan^{-1}x=\frac{-1}{x}+\frac{1}{3x^3}-\frac{1}{5x^5}+\&c.+C.$$

The value of C cannot now be found by making $x=0$, because then the arc $=0$, and the substitution of $x=0$ makes all the terms of the series infinite. If we suppose the arc to be a quadrant $=\frac{\pi}{2}$, then x is infinite, and the terms of the series are each $=0$; by this assumption, $\frac{1}{2}\pi=C$. We have now

$$\tan^{-1}x=\tfrac{1}{2}\pi-\frac{1}{x}+\frac{1}{3x^3}-\frac{1}{5x^5}+\&c.$$

Ex. 4. The differential of the arc whose sine is x is $\frac{dx}{\sqrt{1-x^2}}$. It is proposed to integrate this differential by a series.

By the binomial theorem, $\frac{1}{\sqrt{1-x^2}}=(1-x^2)^{-\frac{1}{2}}=$

$$1+\tfrac{1}{2}x^2+\frac{1.3}{2.4}x^4+\frac{1.3.5}{2.4.6}x^6+\frac{1.3.5.7}{2.4.6.8}x^8+\&c.$$

Hence we have $\sin^{-1}x=\int\frac{dx}{\sqrt{1-x^2}}=$

$$x+\frac{1x^3}{2.3}+\frac{1.3x^5}{2.4.5}+\frac{1.3.5x^7}{2.4.6.7}+\&c.$$

When the arc $=0$, then the sine $=0$; therefore both sides of this equation vanish together, and no constant is wanted to adjust it to equality.

140. The object of integration by series being to obtain approximate values of the integrals when they cannot be found accurately, it is important to have several series, so that we may be able to choose one convergent for a proposed value of x. Ascending series, or those which proceed by positive and increasing powers of x, do not converge sufficiently unless x be a small fraction, as happens with the series of Ex. 2; whilst those which proceed by the negative powers of x, or descending series, converge only so as to be of use when x is a large number.

141. In having recourse to series, it is sufficient to find one, of which the terms are separately integrable, although each may not have the form $Ax^{\frac{m}{n}}dx$; they may have any form, the integral of which can be expressed by an algebraic quantity, or a logarithm, or an arc of a circle; or, in short, any function, the numerical value of which is most readily obtained, provided always that the convergency be such as to admit of the sum of all the terms which are not taken in being rejected, because of its smallness in comparison to the sum of the terms taken in.

In the application of the calculus recourse is only to be had to series as a last resource, when the integral, from its nature, cannot be found in finite terms, or by logarithms or arcs of a circle, which in fact are the sums of infinite series. Indeed it would be very convenient to have various other tables, ready computed, of the value of a function corresponding to given successive values of the variable. The labour of their computation, their necessary great extent, and the infrequency of their use, have hitherto limited this valuable aid in calculation to a table of Napier's Logarithms, in addition to the Trigonometrical Tables.

Integration of Logarithmic Functions.

142. Let it be required to integrate $Pdx\,(\text{l.}\,x)^n$, that is, the nth power of Napier's logarithm of x multiplied by Pdx, P being an algebraic function of x. Here we apply the formula $\int udv=uv-\int vdu$; and making $u=(\text{l.}\,x)^n$, from which we find $du=n\,(\text{l.}\,x)^{n-1}\frac{dx}{x}$, also $dv=Pdx$, we have, making in order to abridge $\int Pdx=N$,

$$\int Pdx\,(\text{l.}\,x)^n=N\,(\text{l.}\,x)^n-n\int\frac{dx}{x}\,(\text{l.}\,x)^{n-1}N.$$

If now we represent the integral $\int\frac{dx}{x}N$ by M, we shall have

$$\int\frac{dx}{x}N(\text{l.}\,x)^{n-1}=M\,(\text{l.}\,x)^{n-1}-(n-1)\int\frac{dx}{x}(\text{l.}\,x)^{n-2}M.$$

By this reduction the proposed integral is made to depend on another of the same kind, in which the exponent of the logarithm is an unit less. Thus, if $P=x^m$, we have

$$\int x^m dx\,(\text{l.}\,x)^n=\frac{x^{m+1}}{m+1}(\text{l.}\,x)^n-\frac{n}{m+1}\int(\text{l.}\,x)^{n-1}x^m dx.$$

By applying the formula to this last integral, and again to the result, we find $\int x^m dx\, (\mathrm{l}.\, x)^n =$

$$x^{m+1}\left\{\frac{(\mathrm{l}.\, x)^n}{m+1} - \frac{n(\mathrm{l}.\, x)^{n-1}}{(m+1)^2} + \frac{n(n-1)\,(\mathrm{l}.\, x)^{n-2}}{(m+1)^3} - \&\mathrm{c.}\right\} + \mathrm{C}.$$

It is evident that this will always terminate when n is a whole number.

143. If n be a whole negative number, we must apply the formula $\int udv = uv - \int vdu$ so as to increase the exponent of the logarithm. Thus in the differential

$$\frac{\mathrm{P}dx}{(\mathrm{l}.\, x)^n} = \frac{\mathrm{P}x}{-n+1} \cdot (-n+1)\,(\mathrm{l}.\, x)^{-n}\ \frac{dx}{x},$$

we make $\mathrm{P}x = u$, and $(\mathrm{l}.\, x)^{-n}\,\dfrac{dx}{x} = dv$, by which $\dfrac{(\mathrm{l}.\, x)^{-m+1}}{-n+1} = v$; for then we have $\displaystyle\int \frac{\mathrm{P}dx}{(\mathrm{l}.x)^n} =$

$$\frac{\mathrm{P}x}{-n+1}\,(\mathrm{l}.\, x)^{-n+1} + \frac{1}{n-1}\int (\mathrm{l}.\, x)^{-n+1}\, d\,(\mathrm{P}x).$$

Let us suppose $\mathrm{P} = x^m$, then this formula becomes

$$\int \frac{x^m dx}{(\mathrm{l}.\, x)^n} = \frac{-x^{m+1}}{(n-1)\,(\mathrm{l}.\, x)^{n-1}} + \frac{m+1}{n-1}\int \frac{x^m dx}{(\mathrm{l}.\, x)^{n-1}}.$$

By repetitions of this transformation, we at last make the proposed integral depend on $\displaystyle\int \frac{x^m dx}{\mathrm{l}.\, x}$. Now, put $x^{m+1} = z$, then $\mathrm{l}.\, x = \dfrac{\mathrm{l}.\, z}{m+1}$ and $x^m dx = \dfrac{dz}{m+1}$, therefore

$$\frac{x^m dx}{\mathrm{l}.\, x} = \frac{dz}{\mathrm{l}. z}.$$

The integral of this last quantity is a transcendental of a peculiar kind, which cannot be otherwise expressed than by infinite series.

Integration of Exponential Functions.

144. It appears from art. 19, that $d(a^x) = \mathrm{l}.\,(a)\, a^x\, dx$, therefore

$$\int a^x dx = \frac{a^x}{\mathrm{l}.\, a} + \mathrm{C}.$$

And because $dx = \dfrac{d(a^x)}{a^x\, \mathrm{l}.a}$; therefore, if V be any algebraic function of a^x, then, putting $a^x = u$, we have $\mathrm{V}dx = \dfrac{\mathrm{V}du}{u\,\mathrm{l}.a}$, an expression which, in respect of u, has an algebraic form.

For example, let $\mathrm{V} = \dfrac{a^x}{\sqrt{1+a^{nx}}}$, then,

$$\int \frac{a^x dx}{\sqrt{1+a^{nx}}} = \frac{du}{\mathrm{l}.\, a\sqrt{1+u^n}}.$$

The integral of this last expression may be found by rules which have been investigated.

Let z be any function of x, then, e being the number of which Nap. log $= 1$, we have $d(ze^x) = e^x dz + e^x\, zdx$, therefore

$$\int e^x\, dx\left(z + \frac{dz}{dx}\right) = ze^x + \mathrm{C}.$$

For example, let $z = x^3 - 1$, then $\dfrac{dz}{dx} = 3x^2$, and

$$\int e^x dx(3x^2 + x^3 - 1) = e^x\,(x^3 - 1) + \mathrm{C}.$$

145. In other cases we may have recourse to the method of integration by parts (art. 134). Thus, let the differential be $x^n a^x\, dx$, then, by the formula $\int udv = uv - \int vdu$, making $u = x^n$, $dv = a^x dx$, we find

$$\int a^x x^n dx = \frac{a^x x^n}{\mathrm{l}.\, a} - \frac{n}{\mathrm{l}.\, a}\int a^x x^{n-1} dx.$$

By treating the differential $a^x x^{n-1} dx$ in the same way, and repeating this as often as necessary, we find $\int a^x x^n dx =$

$$a^x\left\{\frac{x^n}{\mathrm{l}.\, a} - \frac{nx^{n-1}}{(\mathrm{l}.\, x)^2} + \frac{n(n-1)\,x^{n-2}}{(\mathrm{l}.\, a)^3} - \ldots \pm \frac{1\,.\,2\,.\,3\ldots n}{(\mathrm{l}.\, a)^{n+1}}\right\} + \mathrm{C}.$$

146. If the exponent n be negative, by following the same method we may increase the exponent of x. Accordingly, from the formula $\int udv = uv - \int vdu$, making $u = a^x$, and $dv = \dfrac{dx}{x^n}$, we find

$$\int \frac{a^x\, dx}{x^n} = \frac{-a^x}{(n-1)\,x^{n-1}} + \frac{\mathrm{l}.\, a}{n-1}\int \frac{a^x\, dx}{x^{n-1}}.$$

By repeating this transformation, we bring the integral $\displaystyle\int \frac{a^x\, dx}{x^n}$ to depend at last on $\displaystyle\int \frac{a^x\, dx}{x}$.

If we make $a^x = z$, then $x\ \mathrm{l}.\, a = \mathrm{l}.\, z$, and $x = \dfrac{\mathrm{l}.\, z}{\mathrm{l}.\, a}$, and $dx = \dfrac{1}{\mathrm{l}.\, a}\,\dfrac{dz}{z}$; hence $\dfrac{a^x\, dx}{x} = \dfrac{1}{\mathrm{l}.\, a}\,\dfrac{dz}{\mathrm{l}.\, z}$, and

$$\int \frac{a^x\, dx}{x} = \frac{1}{\mathrm{l}.\, a}\int \frac{z}{\mathrm{l}.\, z}.$$

These two integrals involve the same difficulty, and have greatly exercised the ingenuity of analysts. It appears they can only be integrated by infinite series. See on this subject, Lacroix, *Traité du Calcul Differentiel*, vol. iii. No. 1224.

147. If n be a fraction, either of the preceding methods will apply to reduce the exponent of x to some fraction between 0 and $+ 1$ or $- 1$; and then recourse must be had to the method of infinite series.

Whatever has been done in regard to the integral of $x^n a^x dx$, will apply to $\mathrm{P}a^x dx$, supposing P to be any function of x whatever.

Integration of Angular or Circular Functions.

148. There are several ways of integrating expressions which contain circular or trigonometrical functions of a variable.

METHOD I.—Let x be an arc whose sine or cosine is z; for example, let $\sin x = z$, then

$$\cos x = \sqrt{1 - z^2},\ dx = \frac{dz}{\sqrt{1 - z^2}},$$

$$dx \sin^m x \cos^n x = z^m\,(1 - z^2)^{\frac{n-1}{2}}\, dx.$$

1. If n be any odd number, then, in the binomial differential, the radical in the transformed expression disappears.

2. If m is an odd number, the exponent of z without the parenthesis, when increased by unity, will be a multiple of z its exponent, within the parenthesis. Thus one of the conditions of art. 132 is satisfied, and the differential may be made rational.

3. If m and n are even numbers, then the second condition of art. 132 will be satisfied, and the differential may be integrated.

As an example, let the differential be $dx \sin^3 x$. This, by making $z = \sin x$, becomes $\frac{z^3\,dz}{\sqrt{1-z^2}}$. Now, by art. 137,

$$\int \frac{z^3\,dz}{\sqrt{1-z^2}} = \tfrac{1}{3}\cos x\,(2+\sin^2 x) + \mathrm{C}.$$

149. Method II.—The powers of the sine or cosine may be transformed into series, of which the terms are sines or cosines of the multiples of the arc; the terms to be integrated will then have the form $dx \cos kx$, $dx \sin kx$. Now

$$\int dx \cos kx = \frac{1}{k}\sin kx + \mathrm{C};$$

$$\int dx \sin kx = -\frac{1}{k}\cos kx + \mathrm{C}.$$

Ex. 1. Let the differential be $dx \cos^5 x$. By the calculus of sines (Algebra, 258), $\cos^5 x = \frac{1}{16}(\cos 5x + 5\cos 3x + 10\cos x)$; therefore

$\int dx \cos^5 x = \frac{1}{80}\sin 5x + \frac{5}{48}\sin 3x + \frac{5}{8}\sin x + \mathrm{C}.$

This method is often used, because the sines and cosines of the multiples of an arc are more easily found than the powers of the sine and cosine.

Ex. 2. Let the differential be $dx \cos^2 x \sin^3 x$. In the first place, we have (Algebra, art. 260),

$\cos^2 x \sin^3 x = \frac{1}{16}(-\sin 5x + \sin 3x + 2\sin x).$

Hence, multiplying by dx, and integrating,

$\int dx \cos^2 x \sin^3 x = \frac{1}{80}\cos 5x - \frac{1}{48}\cos 3x - \frac{1}{16}\cos x + \mathrm{C}.$

150. Method III.—It has been found (Algebra, art. 270), that e being the base of Napier's logarithms,

$$\cos x = \frac{e^{x\sqrt{-1}} + e^{-x\sqrt{-1}}}{2};$$

$$\sin x = \frac{e^{x\sqrt{-1}} - e^{x\sqrt{-1}}}{2\sqrt{-1}}.$$

These exponential expressions for the sine and cosine enable us to transform differentials containing circular functions into others involving exponential and logarithmic functions, and to integrate by the methods explained (art. 140–145).

151. Method IV.—We may reduce the integration of such a differential as $\sin^m x \cos^n x\, dx$, to that of another in which the indices of the sine or cosine are smaller numbers, by the formula $\int u\,dv = uv - \int v\,du$. For, making $u = \sin^{m-1} x$ and $dv = dx \sin x \cos^n x$, we find $v = -\frac{\cos^{n+1} x}{n+1}$, and

$$\int dx \sin^m x \cos^n x = -\frac{\sin^{m-1}}{n+1} x \cos^{n+1} x$$
$$+ \frac{m-1}{n+1}\int dx \cos^{n+2} x \sin^{m-2} x.$$

From this expression, by putting for $\cos^{n+1} x$, its value $\cos^n x\,(1-\sin^2 x)$, and transposing, we find

(α)

$$\int dx \sin^m x \cos^n x = -\frac{\sin^{m-1} x \cos^{n+1} x}{m+n}$$
$$+ \frac{m-1}{m+1}\int dx \sin^{m-2} x \cos^n x.$$

By resolving the proposed differential into the two factors $dx \cos x \sin^{mx}$ and $\cos^{n-1} x$, and proceeding in the same way, we find

(β)

$$\int dx \sin^m x \cos^n x = \frac{\sin^{m+1} x \cos^{n-1} x}{m+n}$$
$$+ \frac{n-1}{m+n}\int dx \sin^m x \cos^{n-2} x.$$

One of these formulæ serves to depress the exponent of the sine, and the other that of the cosine, and by their joint application the differential may be found when m and n are two positive integer numbers. For example,

$\int dx \sin^3 x \cos^2 x = -\frac{1}{5}\sin^2 x \cos^3 x + \frac{2}{5}\int dx \sin x \cos^2 x,$

$\int dx \sin x \cos^2 x = \frac{1}{3}\sin^2 x \cos x + \frac{1}{3}\int dx \sin x;$

this last term $= -\frac{1}{3}\cos x + \mathrm{C}$, after collecting the terms, we have $\int dx \sin^3 x \cos^2 x =$

$\cos x\,(-\frac{1}{5}\sin^2 x \cos^2 x + \frac{2}{15}\sin^2 x - \frac{2}{15}) + \mathrm{C}.$

152. When m and n are negative, these formulæ require some modification. The first, by changing m into $-n$, gives

(γ)

$$\int \frac{dx \sin^m x}{\cos^n x} = -\frac{\sin^{m-1} x}{(m-n)\cos^{n-1} x}$$
$$+ \frac{m-1}{m-n}\int \frac{dx \sin^{m-2} x}{\cos^n x}.$$

This makes the integral sought depend on that of $\frac{dx \sin x}{\cos^n x}$ or $\frac{dx}{\cos^n x}$, according as m is odd or even. By making $\cos x = z$, the first of these becomes $-\frac{dz}{z^n}$, of which the integral is obvious. The integral of the other will be shown presently in art. 153.

The second of the two general formulæ, by making n negative, and bringing the integral in the second side of the equation to stand alone, and lastly, changing n into $n-2$, gives

(δ)

$$\int \frac{dx \sin^m x}{\cos^n x} = \frac{\sin^{m+1} x}{(n-1)\cos^{n-1} x}$$
$$- \frac{m-n+2}{n-1}\int \frac{dx \sin^m x}{\cos^{n-2} x}.$$

By this the integral sought is reduced to that of $dx \sin^m x$, or to $\frac{dx \sin^m x}{\cos x}$, according as n is even or odd. The first is found by formula (α) (art. 151), the other is presently to be noticed.

153. If we make m or $n = 0$, we have

$$\int dx \sin^m x = \frac{-\cos x \sin^{m-1} x}{m} + \frac{m-1}{m}\int dx \sin^{m-2} x,$$

$$\int dx \cos^n x = \frac{\sin x \cos^{n-1} x}{n} + \frac{n-1}{n}\int dx \cos^{n-2} x,$$

$$\int \frac{dx}{\sin^m x} = \frac{-\cos x}{(m-1)\sin^{m-1} x} + \frac{m-2}{m-1}\int \frac{dx}{\sin^{m-2} x}$$

$$\int \frac{dx}{\cos^n x} = \frac{\sin x}{(n-1)\cos^{n-1} x} + \frac{n-2}{n-1}\int \frac{dx}{\cos^{n-2} x}.$$

154. When the exponents of the sine and cosine are both negative, we multiply the numerator by $\cos^2 x + \sin^2 x = 1$, and have

Inverse Method.

$$\int\frac{dx}{\sin^m x\cos^n x}=\int\frac{dx}{\sin^{m-2}x\cos^n x}+\int\frac{dx}{\sin^m x\cos^{n-2}x},$$

fractions with sin x or cos x in the denominator.

If $m=n$, then because $\sin x\cos x=\frac{1}{2}\sin 2x$, by making $2x=z$, the fraction takes the form of the third of the preceding formulæ.

155. We shall conclude this branch of the subject by integrating four of the more elementary circular functions.

1. To integrate $\frac{dx}{\sin x}$. We observe that $\sin x=2\sin\frac{1}{2}x\cos\frac{1}{2}x$, therefore,

$$\frac{dx}{\sin x}=\frac{dx}{2\sin\frac{1}{2}x\cos\frac{1}{2}x}=\frac{1}{2}\frac{dx\sec^2\frac{1}{2}x}{\tan\frac{1}{2}x}=\frac{d.\tan\frac{1}{2}x}{\tan\frac{1}{2}x},$$

$$\text{and}\int\frac{dx}{\sin x}=\text{l.}\left(\tan\tfrac{1}{2}x\right)+\text{C}.$$

2. To integrate $\frac{dx}{\cos x}$. Putting $\frac{1}{2}\pi$ to denote an arc of 90°, and $x=\frac{1}{2}\pi-z$, we have $dx=-dz$, $\cos x=\sin z$, and

$$\int\frac{dx}{\cos x}=\int\frac{-dz}{\sin z}=-\text{l.}\tan\tfrac{1}{2}z=\text{l.}\frac{1}{\tan\frac{1}{2}z}+\text{C}.$$

Now $\frac{1}{\tan\frac{1}{2}z}=\frac{1}{\tan(\frac{1}{4}\pi-\frac{1}{2}x)}=\tan\left(\frac{1}{4}\pi+\frac{1}{2}x\right)$.

Therefore $\int\frac{dx}{\cos x}=\text{l.}\tan\left(\frac{1}{4}\pi+\frac{1}{2}x\right)+\text{C}$.

This and the preceding integral may be otherwise expressed thus,

$$\int\frac{dx}{\sin x}=\tfrac{1}{2}\text{l.}\frac{1-\cos x}{1+\cos x}+\text{C}.$$

$$\int\frac{dx}{\cos x}=\tfrac{1}{2}\text{l.}\frac{1+\sin x}{1-\sin x}+\text{C}.$$

3. $\int\frac{dx}{\tan x}=\int\frac{dx\cos x}{\sin x}=\text{l.}(\sin x)+\text{C}.$

4. $\int dx\tan x=\int\frac{dx\sin x}{\cos x}=\text{l.}\frac{1}{\cos x}+\text{C}.$

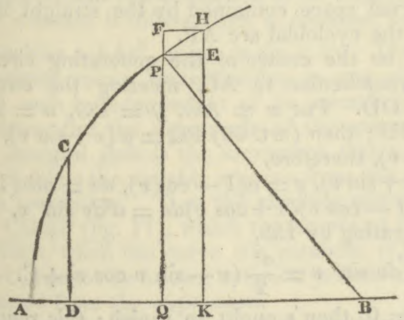
Applications of the Integral Calculus.

Before we proceed farther in the explanation of the theory of the calculus, we shall apply its principles to some of the more important problems in Geometry.

Quadrature of Curves.

156. Let $\text{AQ}=x$, $\text{PQ}=y$, be the co-ordinates of a curve, of which AB is the axis; and let the area CDQP, comprehended between CD, an ordinate given in position, and PQ any other ordinate, be denoted by s. We have found (art. 69) that $ds=ydx$; therefore, in any curve whatever,

Fig. 21.



$$\text{area } s=\int ydx$$

Ex. 1. Let the curve be a parabola, of which p is the parameter. By the nature of the curve, $y^2=px$, and $y=p^{\frac{1}{2}}x^{\frac{1}{2}}$, and $ydx=p^{\frac{1}{2}}x^{\frac{1}{2}}dx$; therefore, taking the integral by art. 104,

$$s=\int ydx=\tfrac{2}{3}p^{\frac{1}{2}}x^{\frac{3}{2}}+c=\tfrac{2}{3}yx+\text{C}\ldots\ldots\ldots(1)$$

Let $\text{AD}=a$, $\text{CD}=b$; when $s=0$, then $x=a$, $y=b$. These values being substituted in the above general expression for the area, it becomes

$$0=\tfrac{2}{3}ab+\text{C}.$$

If we now subtract the sides of equation (2) from the corresponding sides of (1), the indeterminate constant C will disappear, and we shall have

$$s=\tfrac{2}{3}(xy-ab).$$

This is a convenient way of eliminating the indeterminate constant. If A, the origin of the abscissa x, be the vertex of the parabola, and if the area s be supposed to begin at the vertex, then $a=0$, $b=0$; and the area comprehended between the axis, an ordinate, and the curve, is $\frac{2}{3}xy$, that is, $\frac{2}{3}$ of the circumscribing parallelogram.

Ex. 2. Let the curve be a circle Apa (see fig. 7, art. 66), of which Aa is a diameter. Suppose the origin of co-ordinates to be at O, the centre; let Ob be the radius perpendicular to OA; put $\text{OQ}=x$, $p\text{Q}=y$, OA the radius $=a$, the space $\text{OQ}pb=s$; by the nature of the circle $x^2+y^2=a^2$, and $y=\sqrt{a^2-x^2}$; hence

$$s=\int ydx=\int dx\sqrt{a^2-x^2}.$$

This integral cannot be expressed in finite algebraic terms; therefore recourse must be had to an infinite series. By the binomial theorem, $\sqrt{a^2-x^2}=(a^2-x^2)^{\frac{1}{2}}=$

$$a-\frac{1\,.\,x^2}{2\,.\,a^2}-\frac{1\,.\,1\,.\,x^4}{2\,.\,4\,a^3}-\frac{1\,.\,1\,.\,3\,.\,x^6}{2\,.\,4\,.\,6\,a^5}-\text{\&c.}$$

Each term of this series being multiplied by dx, and the integral taken, we have

$$s=ax-\tfrac{1}{2}\cdot\frac{x^3}{3a}-\frac{1.1}{2.4}\cdot\frac{x^5}{5a^3}-\frac{1.1.3}{2.4.6}\cdot\frac{x^7}{5a^5}-\text{\&c.}+\text{C}.$$

To determine C, we consider that when $x=0$, then $s=0$, these values make both sides of the equation $=0$; therefore $\text{C}=0$; when $x=a$, then $s=\frac{1}{4}$ of the area of the circle; therefore the area of a circle whose radius $=a$ is

$$4a^2\left(\frac{1}{1}-\frac{1}{2}\cdot\frac{1}{3}-\frac{1.1}{2.4}\cdot\frac{1}{5}-\frac{1.1.3}{2.4.6}\cdot\frac{1}{7}-\text{\&c.}\right).$$

This series converges slowly, so that a considerable number of terms would be required to give its value near the truth. If we make $x=\cos$ arc 60°, then, drawing the radius Op, the area OQpb will manifestly be made up of the sector POb, which is $\frac{1}{12}$ of the area of the circle, and the triangle OQp, which is $\frac{1}{2}\text{OQ}\,.\,p\text{Q}=\frac{\sqrt{3}}{8}a^2$.

Putting $\frac{a}{2}$ for x in the series, it will now converge much faster, and the sum of seven of its terms will be $\cdot4783057a^2$, from which subtracting $\frac{\sqrt{3}}{8}a^2=\cdot2165063a^2$, there remains $\cdot2617994a^2$ for $\frac{1}{12}$ of the area, and $3\cdot1415928a^2$ for the whole area of the circle. We have found this number by a less laborious calculation, in ALGEBRA, 273. We may make A, one end of the diameter (fig. 7, art. 66), the origin of the co-ordinates, so that $\text{AQ}=x$, $pq=y$, segment ApQ$=s$ · then, because $y=\sqrt{2ax-x^2}$, the area

$$s=\int dx\sqrt{2ax-x^2}=\int dx\sqrt{2ax}\left(1-\frac{x}{2a}\right)^{\frac{1}{2}}.$$

The integral of this expression will be had by converting $\left(1-\frac{x}{2a}\right)^{\frac{1}{2}}$ into a series, then multiplying the terms separately by $dx\sqrt{2ax}$, and integrating.

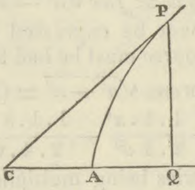
Ex. 3. To find the area of the elliptic segment APQ (fig. 7, art. 66). Let OA, the semitransverse, $=a$, OB, the semiconjugate, $=b$, $\text{AQ}=x$, $\text{PQ}=y$, the area $\text{APQ}=s$. By the nature of the ellipse, $y=\frac{b}{a}\sqrt{2ax-x^2}$; therefore the elliptic segment

$$s=\int ydx=\frac{b}{a}\int dx\sqrt{2ax-x}.$$

Let APa be a semicircle on the same axis, and let s' denote the segment cut off by the ordinate pPQ, which is common to both curves. We found in last example that $s'=\int dx\sqrt{2ax-x^2}$; therefore $s=\frac{b}{a}s'$. Thus it appears that the area of APQ, any segment of an ellipse, has to the area of ApQ the corresponding segment of the circumscribing circle, the constant ratio of the lesser axis to the greater. Neither of the integrals require a constant, because both vanish when $x=0$.

Ex. 4. To find the area of the hyperbolic sector PCA, C being the centre of the hyperbola, and CA the semitransverse axis.

Fig. 22.



Draw the ordinate PQ; let the semitransverse axis $\text{CA}=a$, the semiconjugate axis $=b$, $\text{CQ}=x$, $\text{PQ}=y$, the sector $\text{PAC}=s$.

Because $s=$ triangle CPQ — space APQ $=\frac{1}{2}xy-\int ydx$; therefore $ds=\frac{1}{2}xdy+\frac{1}{2}ydx-ydx=\frac{1}{2}(xdy-ydx)$.

Now, by the nature of the curve, $y=\frac{b}{a}\sqrt{x^2-a^2}$, therefore $dy=\frac{b}{a}\frac{xdx}{\sqrt{x^2-a^2}}$, and

$$ds=\frac{b}{2a}\left\{\frac{x^2dx}{\sqrt{x^2-a^2}}-dx\sqrt{x^2-a^2}\right\}=\frac{1}{2}ab\frac{dx}{\sqrt{x^2-a^2}}.$$

Now, by art. 130, $\int\frac{dx}{\sqrt{x^2-a^2}}=\text{l.}\,(x+\sqrt{x^2-a^2})+\text{C}$.

$$\text{Therefore } s=\frac{ab}{2}\,\text{l.}\,(x+\sqrt{x^2-a^2})+\text{C}.$$

Here C denotes an indefinite constant: To determine its value, we consider that when $x=a$, then $s=0$; therefore in this particular case,

$$0=\frac{ab}{2}\,\text{l.}\,a+\text{C}.$$

Hence, by subtracting equals from equals, and observing that the difference of two logarithms is the logarithm of their quotient, we eliminate C, and have

$$s=\frac{ab}{2}\,\text{l.}\,\frac{x+\sqrt{x^2-a^2}}{a}.$$

Because $\sqrt{x^2-a^2}=\frac{ay}{b}$, therefore also

$$s=\frac{ab}{2}\,\text{l.}\left\{\frac{x}{a}+\frac{y}{b}\right\}.$$

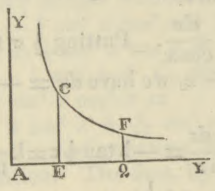
Ex. 5. To find the area of s, the hyperbolic space APQ' we have $s=$ triangle CPQ — sector CAP, or

$$s=\tfrac{1}{2}xy-\frac{ab}{2}\,\text{l.}\left\{\frac{x}{a}+\frac{y}{b}\right\}.$$

Ex. 6. Let the curve be an equilateral hyperbola, of which AX, AY are the asymptotes: To find s, the area included by the hyperbolic arc CF, the straight lines CE, FQ, which are parallel to one asymptote, and EQ, the segment of the other asymptote between them; suppose CE one of the parallels to be given in position. Put $\text{AE}=a$, $\text{EC}=b$, $\text{AQ}=x$, $\text{EQ}=y$. By the nature of the curve, $xy=ab$; hence $y=\frac{ab}{x}$, and

$$s=ydx=ab\frac{dx}{x}=ab\,\text{l.}\,x+\text{C}.$$

Fig. 23.



Now, when $x=a$, then $s=0$; in this case $0=ab\,\text{l.}\,a+\text{C}$, or $\text{C}=-ab\,\text{l.}\,a$; hence, substituting for C its value, and putting $\text{l.}\,\frac{x}{a}$ for $\text{l.}\,x-\text{l.}\,a$, we have

$$s=ab\,\text{l.}\,\frac{x}{a}.$$

From this formula we find $\text{l.}\,\frac{x}{a}=\frac{s}{ab}$. Thus it appears that Napier's logarithm of any number $\frac{x}{a}$ may be expressed by a hyperbolic area; hence it has happened that the logarithms of his system have been called *hyperbolic.*

If M be the *modulus* of any system, the log of $\frac{x}{a}$ in that system will be $\text{M l.}\,\frac{x}{a}$; therefore, in any system of which the modulus is M, we have

$$\log.\,\frac{x}{a}=\frac{\text{M}}{ab}\,s.$$

Thus we see that logarithms of any system may be expressed geometrically by hyperbolic areas, and therefore that the name *hyperbolic logarithms* cannot with propriety be given to one kind of logarithms rather than to another.

Ex. 7. Let the curve be the cycloid (fig. 9, art. 66), of which AC is the axis, and AH a perpendicular to the axis at the vertex A. From any point in the curve draw PG perpendicular to AH: it is proposed to find s, the area of the external space contained by the straight lines AG, GP, and the cycloidal arc AP.

Let O be the centre of the generating circle; draw PDQ perpendicular to AC, meeting the circle in D, and join OD. Put $x=\text{AG}$, $y=\text{PG}$, $a=\text{AO}$, $v=$ angle AOD; then (art. 66) $\text{PQ}=a(v+\sin v)$, $\text{AQ}=a(1-\cos v)$, therefore,

$x=a(v+\sin v)$, $y=a(1-\cos v)$, $dx=adv(1+\cos v)$,
$ds=a^2(1-\cos v)(1+\cos v)dv=a^2dv\sin^2 v$,
and integrating by 153,

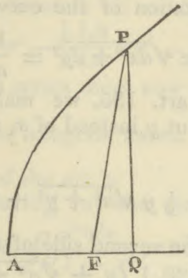
$$s=a^2\int dv\sin^2 v=\frac{a^2}{2}(v-\sin v\cos v)+\text{C}.$$

When $v=0$, then s ought to vanish; this requires that $\text{C}=0$. Putting now the arc AD for av, and $\text{DQ}\cdot\text{OQ}$ for $a^2\sin v\cos v$, we have

$$s=\tfrac{1}{2}\,\text{AO}\cdot\text{arc AD}-\tfrac{1}{2}\,\text{DQ}\cdot\text{OQ}=\text{circ. seg. ADQ}.$$

Ex. 8. To find the area contained by AF, a line drawn from the focus of a parabola to the vertex, FP a line drawn to any point of the curve, and the intercepted arc AP.

Fig. 24.



Let a denote the parameter $= 4\text{AF}$, $u =$ the angle AFP, $r = \text{FP}$, $s =$ the parabolic sector APF. Draw PQ perpendicular to the axis AF. By the nature of the curve, $\text{PF} = \text{AQ} + \text{AF}$. Now, supposing PFA to be an obtuse angle, $\text{FQ} = -r \cos v$, $\text{AQ} = \frac{1}{4}a - r\cos v$, $\text{AF} = \frac{1}{4}a$, therefore, $r = \frac{1}{2}a - r\cos v$, and $r(1+\cos v) = \frac{1}{2}a$; hence, since $1 + \cos v = 2\cos^2 \frac{1}{2}v$, $r = \frac{a}{4}\,\frac{1}{\cos^2 \frac{1}{2}v}$.

Now, by formula 3, article 69, $ds = \frac{1}{2}r^2 dv$, therefore

$$ds = \frac{a^2}{16}\,\frac{\frac{1}{2}dv}{\cos^4\frac{1}{2}v}.$$

To integrate this differential, we consider that

$$\frac{\frac{1}{2}dv}{\cos^2\frac{1}{2}v} = \sec^2\tfrac{1}{2}v\,\frac{dv}{2} = d(\tan\tfrac{1}{2}v);$$

and that $\frac{1}{\cos^2\frac{1}{2}v} = \sec^2\frac{1}{2}v = 1 + \tan^2\frac{1}{2}v$;

therefore, multiplying these equations, we get

$$\frac{\frac{1}{2}dv}{\cos^4\frac{1}{2}v} = d(\tan\tfrac{1}{2}v) + \tan^2\tfrac{1}{2}v\; d(\tan\tfrac{1}{2}v);$$

and hence, integrating by the rule art. 104, we find

$$\int\frac{\frac{1}{2}dv}{\cos^4\frac{1}{2}v} = \tan\tfrac{1}{2}v + \tfrac{1}{3}\tan^2\tfrac{1}{2}v + \text{C}.$$

Observing now that when $v = 0$, then $s = 0$; therefore $\text{C} = 0$, and we have

$$s = \frac{a^2}{16}(\tan\tfrac{1}{2}v + \tfrac{1}{3}\tan^3\tfrac{1}{2}v).$$

This integral might have been found by the formula of art. 153; not so easily, however. The formula here found is wanted in the astronomy of comets.

157. Since the area of any plane curve is expressed by an integral $\int ydx$, in which y the ordinate is some function of x the absciss, so, on the other hand, any integral may be represented geometrically by the area of a curve. The geometrical representation of an integral shows distinctly wherein it differs from a common analytic function, such as $a + bx^n$, or ax, or $\sin x$, &c. These last have determinate values corresponding to any given value of x, and each is independent of its preceding and following values; but the magnitude of the space represented by an integral $\int ydx$ is the increment that a certain area receives while the variable x passes from one state of magnitude to another. Thus the absolute magnitude of the space CDQP (fig. 11), which represents an integral $\int ydx$, and which, when the curve is a parabola, is expressed by $\frac{2}{3}xy + \text{C}$, cannot be known before C is determined, or else eliminated from the expression.

Whatever be the nature of the curve, the integral $\int ydx =$ space CPQD is correctly indicated, so as to admit of being computed, when we say that it is generated while the variable x increases from any value $=$ AD, to another value $=$ AQ, the lines AD, AQ being supposed given in magnitude, and the relation between x and y known. The same thing is briefly indicated by this notation:

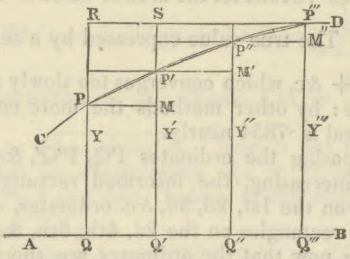
$$\text{area CPQD} = \int_a^x ydx,$$

in which a and x denote the lines AD and AQ.

From what has been shown it appears that an integral is an indeterminate quantity, the result of a change in the value of its variable; and that to know its absolute value we must know the values of the variable at its commencement and completion.

158. The analogy between a curvilineal area and an integral indicates a general method of finding its numerical value to any degree of nearness. Supposing y to be any function of x, let it be proposed to find the integral $\int ydx$ between $x = a$ and $x = b$.

Fig. 25.



Let CPD be a curve, of which the co-ordinates are x and y. In the axis AB, take $\text{AQ} = a$, the least value of x, and $\text{AQ}''' = b$, its greatest value, and draw the ordinates PQ, P'''Q'''. The area PQQ'''P''' will be the geometrical expression of the integral between the proposed limits; and by whatever means that area can be found, the same will apply to the determination of the integral.

Divide QQ''' into any number of equal parts at the points Q′, Q″, &c. and draw the ordinates P′Q′, P″Q″, &c. These will divide the whole figure into the spaces PP′Q′Q, P′P″Q″Q′, &c. Let a series of rectangles PQ′, P′Q″, P″Q''' be formed, each having the least of two adjoining ordinates for a side: these will fall within the curve, supposing it to be entirely concave or convex towards the axis. Let another series P′Q, P″Q′, P'''Q″ be constructed, each having the longest of two adjoining ordinates for a side: the aggregate of these will exceed the area of the curve. The length of the base of each rectangle will be known, and, from the nature of the curve, its height will also be known; hence the areas of all the rectangles may be found. The sum of the areas of the inscribed rectangles will be less than the integral, and the sum of the areas of the circumscribing rectangles will be greater. The difference between these sums is the rectangle PMSR, which, by supposing its base $\text{PM} = \text{QQ}'$ to be sufficiently small, may be less than any assignable space. Thus an approximate value of the integral may be found, which shall differ from the truth by as small a quantity as we please.

Draw the chords PP′, P′P″, P″P''', thus forming a series of trapeziums, which will differ from the curvilineal area by less than the sum of either the inscribed or circumscribing parallelograms, and will be a mean between them. This will be a nearer approximation than either sum to the integral.

As an example of the application of this method, let it be proposed to approximate to the integral $\int_0^1 \frac{dx}{1+x^2}$, that is, to the arc whose tangent is x, between the values of $x = 0$ and $x = 1$, which arc is $\frac{1}{4}$ of a semicircle, the radius being supposed $= 1$. In this case the equation of the curve is $y = \frac{1}{1+x^2}$. Let us suppose the base QQ‴ to be divided into ten equal parts; then, making $x = 0$, $x = \cdot 1$, $x = \cdot 2$, &c. to $x = 1$, we obtain eleven equidistant ordinates or values of y as follows:

The 1*st*,	1.00000	The 7*th*,	·73529
2*d*,	·99010	8*th*,	·67114
3*d*,	·96154	9*th*,	·60975
4*th*,	·91743	10*th*,	·55249
5*th*,	·86207	11*th*,	·50000
6*th*,	·80000		

By the elements of geometry, the area of the rectilineal figure formed by the trapeziums is found by adding together all the ordinates except the first and last, and half the sum of the first and last, and multiplying the result by the common breadth of the trapeziums, which is ·1. This gives ·784981 for the area or value of the integral $\int_0^1 \frac{dx}{1+x^2}$. The true value expressed by a series is $1 - \frac{1}{3} + \frac{1}{5} - \frac{1}{7} +$ &c. which converges too slowly to be of any practical use: by other methods the more correct value of the integral is ·7854 nearly.

159. Supposing the ordinates PQ, P′Q′, &c. to go on continually increasing, the inscribed rectangles will be constructed on the 1st, 2d, 3d, &c. ordinates, and the circumscribing rectangles on the 2d, 4th, 6th, &c.

Observing now that the ordinates are the values of y corresponding to AQ, AQ′, &c. values of x, which differ by the common interval QQ′, we have manifestly the following rule for approximating to an integral $\int ydx$ between the limits of $x = \mathrm{AQ} = a$ and $x = \mathrm{AQ}''' = b$. Divide the interval $\mathrm{QQ}''' = b - a$ into n equal parts, each equal to h.

Find Y, Y′, Y″, ... $\mathrm{Y}^{(n)}$ the particular values of Y corresponding to $x = a$, $x = a + h$, $x = a + 2h \ldots$; $x = a + nh = b$.

Then, supposing the ordinates to go on increasing,

$$\int_a^b ydx > h\,(\mathrm{Y} + \mathrm{Y}' + \mathrm{Y}'' \ldots\ldots + \mathrm{Y}^{(n-1)});$$

$$\int_a^b ydx < h\,(\mathrm{Y}' + \mathrm{Y}'' + \mathrm{Y}''' \ldots\ldots + \mathrm{Y}^{(n)}).$$

The difference of these is $h(\mathrm{Y}^{(n)} - \mathrm{Y})$, which, by taking x sufficiently small, may be as small as we please. We may reason in the same way when the ordinates form a decreasing series. If they first increase and then decrease, the interval $b - a$ may be divided into two or more portions, such that y increases or decreases continually from one end of each to the other.

Whatever be the values of y, provided they be always finite from $x=a$ to $x=b$, putting for them Y, Y′, Y″ .. $\mathrm{Y}^{(n)}$, we have

$$\int_a^b ydx \,. = \mathrm{Y}h + \mathrm{Y}'h + \mathrm{Y}''h \ldots\ldots + \mathrm{Y}^{n-1}\,h.$$

Leibnitz and his followers considered the integral $\int ydx$ as the sum of the infinitely little elements Yh, Y′h, &c. Hence the origin of the terms integral, to integrate, integration, &c. When h is infinitely little, and represented by dx, the differential of x, then ydx is the differential of the integral.

Rectification of Curves.

160. We have found (art. 72) that z being any arc of a curve referred to an axis by rectangular co-ordinates x, y, the differential of the arc, viz. $dz, = \sqrt{dx^2 + dy^2}$. We are now to apply the calculus to particular curves.

Ex. 1. Let the curve be a parabola (fig. 16) of which the parameter $= 2a$, the absciss $\mathrm{AQ} = x$, the ordinate $\mathrm{PQ} = y$. The equation of the curve, $2ax = y^2$, gives

$$adx = ydy \text{ and } dz = \sqrt{dx^2 + dy^2} = \frac{1}{a} dy \sqrt{a^2 + y^2}.$$

If in formula B, art. 135, we make $m = 1$, $n = 2$, $p = \frac{1}{2}$, $b = 1$, and put y instead of x, and a^2 instead of a, we have

$$\int dy \sqrt{a^2 + y^2} = \tfrac{1}{2}\, y \sqrt{a^2 + y^2} + \tfrac{1}{2}\, a^2 \int \frac{dy}{\sqrt{a^2 + y^2}}.$$

The integral in the second side of this equation is, by the formula of art. 130, $\mathrm{l.}\,(y + \sqrt{a^2 + y^2}) + \mathrm{C}$; therefore $z = \frac{y}{2a} \sqrt{a^2 + y^2} + \frac{a}{2}\,\mathrm{l.}\,(y + \sqrt{a^2 + y^2}) + \mathrm{C}$.

If we suppose z to begin at the vertex, then, when $z = 0$, $y = 0$; therefore $\mathrm{C} = -\frac{a}{2}\,\mathrm{l.}\,a$, and

$$z = \frac{y}{2a}\sqrt{a^2 + y^2} + \frac{a}{2}\,\mathrm{l.}\,\frac{y + \sqrt{a^2 + y^2}}{a}.$$

Ex. 2. Let the curve be the second cubic parabola of which the equation is $y^3 = ax^2$. In this case the general formula gives

$$dz = dy \sqrt{1 + \frac{9y}{4a}} \text{ and } z = \tfrac{8}{27} \sqrt{\left(1 + \frac{9y}{4a}\right)^3} + \mathrm{C}.$$

This curve is perfectly rectifiable. Indeed it is the evolute of the parabola (art. 81, ex. 1).

Ex. 3. Let the curve be a circle (fig. 7), of which the radius $\mathrm{OA} = a$. Reckoning the co-ordinates from the centre, let $\mathrm{OQ} = x$, $p\mathrm{Q} = y$, $b\mathrm{P} = z$. The equation of the curve is $x^2 + y^2 = a^2$; hence $y = \sqrt{a^2 - x^2}$, $dy = -\frac{xdx}{\sqrt{a^2 - x^2}}$ and $dz = \frac{adx}{\sqrt{a^2 - x^2}}$. This integral cannot be otherwise expressed than by an infinite series. We have already found it (art. 139, ex. 4) on the supposition that the radius $= 1$; when the radius $= a$, we have only to put $\frac{x}{a}$ instead of x, thence we get

$$z = x + \frac{1}{2} \cdot \frac{x^3}{3a^2} + \frac{1.3}{2.4} \cdot \frac{x^5}{5a^4} + \frac{1.3.5}{2.4.6} \frac{x^7}{7a^6} + \&c.$$

There is no constant wanted; because, from the nature of the case, z and x begin together.

From this example, also from ex. 2, art. 156, and ex. 2, art. 139, it appears that the quadrature, also the rectification of the circle, is equivalent to the determination of any one of these integrals, $\int dx \sqrt{1 - x^2}$, $\int \frac{dx}{\sqrt{1 - x^2}}$, $\int \frac{dx}{1 + x^2}$, which is a problem in pure analysis, and which does not seem to admit of a solution in finite terms. The solution of that celebrated geometrical problem is therefore hopeless.

Ex. 4. Let the curve be an ellipse (fig. 7), of which the semitransverse axis $\mathrm{OA} = 1$, the semiconjugate $\mathrm{OB} = b$, the eccentricity, which is $\sqrt{1. - b^2}, = e$. Let O the centre be the origin of the co-ordinates $\mathrm{OQ} = x$, $\mathrm{PQ} = y$; and, reckoning the arc from the extremity of the lesser axis, let $\mathrm{BP} = z$. By the nature of the curve, $y = b\sqrt{1 - x^2}$, therefore $dy = \frac{-bxdx}{\sqrt{1 - x^2}}$, and

$$dz = \sqrt{dx^2 + dy^2} = \frac{dx\sqrt{1 - (1 - b^2)x^2}}{\sqrt{1 - x^2}} = \frac{dx\sqrt{1 - e^2x^2}}{\sqrt{1 - x^2}}.$$

The integral of this differential is of such a nature as not to admit of being expressed either by arcs of a circle or logarithms. Therefore it can only be expressed by infinite series.

By the binominal theorem $\sqrt{1 - e^2x^2} =$

$$1 - \tfrac{1}{2} e^2x^2 - \frac{1.1}{2.4} e^4x^4 - \frac{1.1.3}{2.4.6} e^6x^6 - \frac{1.1.3.5}{2.4.6.8} e^8x^8 - \&c.$$

The terms of this series must now be multiplied each by $\frac{dx}{\sqrt{1 - x^2}}$, and the integrals found, and their sum will express the length of the arc z.

The integrals, leaving out the numeral co-efficients, will all have the form $\int \frac{x^{2n}dx}{\sqrt{1 - x^2}}$; therefore they will be found by the second formula of article 137. Thus, putting φ for the arc whose sine is x, we have

$$\int \frac{dx}{\sqrt{1 - x^2}} = \varphi,$$

$$\int \frac{x^2dx}{\sqrt{1 - x^2}} = -\tfrac{1}{2} x \sqrt{1 - x^2} + \tfrac{1}{2} \varphi,$$

$$\int \frac{x^4dx}{\sqrt{1 - x^2}} = -\left(\tfrac{1}{4} x^3 + \frac{1.3}{2.4} x\right)\sqrt{1 - x^2} + \frac{1.3}{2.4} \varphi,$$

&c.

These integrals being multiplied by their respective coefficients, we have the elliptic arc $z =$

$$\varphi\left(1 - \frac{1.1}{2.2} e^2 - \frac{1.1.3}{2.2.4.4} e^4 - \frac{1.1.3.3.5}{2.2.4.4.6.6} e^6 - \&c.\right)$$
$$+ \tfrac{1}{2} e^2 \left(\tfrac{1}{2} x \sqrt{1 - x^2}\right)$$
$$+ \frac{1.1}{2.4} e^4 \left(\tfrac{1}{4} x^3 + \frac{1.3}{2.4} x\right)\sqrt{1 - x^2}$$
$$+ \frac{1.1.3}{2.4.6} e^6 \left(\tfrac{1}{6} x^5 + \frac{1.3}{4.6} x^3 + \frac{1.3.5}{2.4.6} x\right)\sqrt{1 - x^2}$$
$$+ \&c.$$

Here no constant is wanted, because the functions on both sides of $=$ vanish when $x = 0$, as they should.

If we make $x = 1$, then all the terms multiplied by $\sqrt{1-x^2}$ vanish; and as in this case $\varphi =$ a quadrant $= \frac{1}{2} \pi$, we get the elliptic quadrant AB $=$

$$\tfrac{1}{2} \pi \left(1 - \frac{1.1}{2.2} e^2 - \frac{1.1.3}{2.2.4.4} e^4 - \frac{1.1.3.3.5}{2.2.4.4.6.6} e^6 - \&c.\right)$$

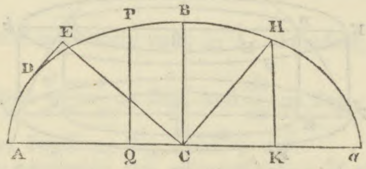
This expression converges pretty fast when e is small, but when e is nearly $= 1$, it is hardly of any use. To have a complete solution, we ought to have another series suited to the case of $e = 1$ nearly. Our limits, however, do not admit of our entering on its investigation here. The integration of the differential $\frac{dx\sqrt{1 - e^2x^2}}{\sqrt{1 - x^2}}$, which, putting φ for the arc whose sine $= x$, may be also expressed thus, $d\varphi\sqrt{1 - e^2 \sin^2 \varphi}$, has greatly engaged the attention of mathematicians. On this subject consult the works quoted in the conclusion of our History of Fluxions, page 640.

The length of a hyperbolic arc may be found exactly in the same way as that of the ellipse from its equation $y = b\sqrt{x^2 - 1}$.

161. We shall here explain the remarkable property of the ellipse, first discovered by Fagnano, as has been mentioned, page 640, and which has proved the fertile germ of some of the finest discoveries in the modern analysis.

In the ellipse ABa, let DE be a tangent at any point D in the curve, draw CE from the centre perpendicular to the tangent, and parallel to it draw the semidiameter CH, which will be the conjugate to that drawn from C through D; and draw HK perpendicular to the axis. Let CA $= 1$, CB $= b$, $\sqrt{1 - b^2}$, the eccentricity, $= e$. Make the perpendicular CE $= p$, the tangent DE $= t$, the angle ACE $=$ CHK $= \varphi$, and the arc AD $= z'$. By the nature of the ellipse, $CA^2 \cdot HK^2 = CB^2 (CA^2 - CK^2)$, that is, because HK $=$ CH $\cos \varphi$, and CK $=$ CH $\sin \varphi$, $CH^2 \cos^2 \varphi = b^2(1 - CH^2 \sin^2 \varphi)$, and hence $b^2 = CH^2 (\cos^2 \varphi + b^2 \sin^2 \varphi) = CH^2 (1 - e^2 \sin^2 \varphi)$, and $CH = \frac{b}{\sqrt{1 - e^2 \sin^2 \varphi}}$.

Fig. 26.



Now, by the nature of the ellipse, $CH = \frac{CA \cdot CB}{CE} = \frac{b}{p}$, therefore $p = \sqrt{1 - e^2 \sin^2 \varphi}$. Now it has been shown (art. 75) that in every curve $d(z + t) = pd\varphi$, and therefore $z + t = \int pd\varphi$; hence, in the ellipse, $z' + t = \int \varphi\sqrt{1 - e^2 \sin^2 \varphi}$.

In the semi-axis CA take CQ $=$ CA $\cdot \sin$ ECA $= \sin \varphi$, draw the ordinate QP, and put $z =$ elliptic arc BP. By what was shown in last article, $dz = d\varphi \sqrt{1 - e^2 \sin^2 \varphi}$, and $z = \int d\varphi \sqrt{1 - e^2 \sin^2 \varphi}$; thence it appears that the functions $z' + t$ and z have the same differential, therefore they can only differ by a constant, that is, $z' + t = z + C$. Now when $z = 0$, then $\varphi = 0$, and $z' = 0$, also $t = 0$; therefore the variables z, z', and t' begin together, and the constant $C = 0$; thus we have $z' + t = z$ and $z - z' = t$. Hence we have this very remarkable property of an ellipse. At any point D in the curve draw a tangent DE, and from the centre C draw CE perpendicular to the tangent. In CA take CQ $=$ CA $\cdot \sin$ ECA; draw the ordinate PQ. *The difference of the elliptic arcs* BP, AD (*that is*, BP — AD), *is equal to the tangent* DE. *This is in substance Fagnano's theorem. Hence it follows that any arc of an ellipse being given, another may be found by a geometrical construction, such, that their difference shall be an assignable straight line.*

We have found (art. 75) that in all curves $t = \frac{-dp}{d\varphi}$. In the ellipse $p = \sqrt{1 - e^2 \sin^2 \varphi}$ and $\frac{dp}{d\varphi} = \frac{-e^2 \sin \varphi \cos \varphi}{\sqrt{1 - e^2 \sin^2 \varphi}}$. Therefore, without any reference to the length of the tangent,

$$z - z' = \frac{e^2 \sin \varphi \cos \varphi}{\sqrt{1 - e^2 \sin^2 \varphi}}.$$

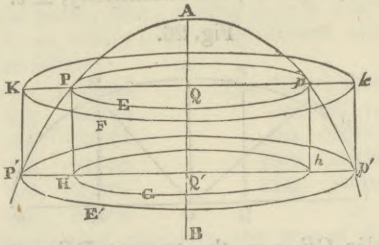
There are corresponding properties of the hyperbola, but our limits forbid our entering on them.

Cubature of Solids.

162. Let AB be the axis of any plane curve APP′, and PQ, P′Q′ ordinates perpendicular to the axis; draw PH perpendicular to the ordinate P′Q′, and PK perpendicular to PQ. Conceive now the plane figure AP′Q′ to revolve about the axis AB; the curve AP will generate a solid AP′E′p', called a *solid of revolution*; and the rectangles

PQQ′H, P′Q′QK will generate cylinders whose bases are circles PEp, P′E′p', and common altitude QQ′.

Fig. 27.



Put AQ $= x$, AQ′ $= x'$, PQ $= y$, P′Q′ $= y'$; the solid generated by the space APQ $= s$, that generated by AP′Q′ $= s'$. Let $\pi = 3{\cdot}1416 =$ the area of a circle whose radius is 1. The content of the cylinder whose base is PEp will be $\pi(x' - x)y^2$, and that of the cylinder whose base is P′E′p' will be $\pi(x' - x)y'^2$.

The solid generated by the curvilineal space PQQ′ ′ being greater than the cylinder whose base is PEp, but less than the cylinder whose base is P′E′p', we have

$$s' - s > \pi(x' - x)y^2, \text{ and } s' - s < \pi(x' - x)y'^2;$$

$$\text{therefore } \frac{s' - s}{x' - x} > \pi y^2, \text{ and } \frac{s' - s}{x - x} < \pi y'^2.$$

Conceive now the circle P′E′p' to approach continually to the circle PEp; they will ultimately coincide and be equal; therefore πy^2 is the limit of $\frac{s' - s}{x' - x}$, and consequently $\frac{ds}{dx} = \pi y^2$, and

$$ds = \pi y^2 dx, \text{ and } s = \pi \int y^2 dx.$$

By this formula the content of a solid of revolution generated by any given plane curve may be found.

163. Ex. 1. Let the solid be a paraboloid generated by the revolution of a parabola AP about its axis AQ. By the nature of the curve, $y^2 = ax$; therefore, in this case,

$$s = \pi \int ax dx = \tfrac{1}{2}\pi ax^2 + \mathrm{C} = \tfrac{1}{2}\pi xy^2 + \mathrm{C}.$$

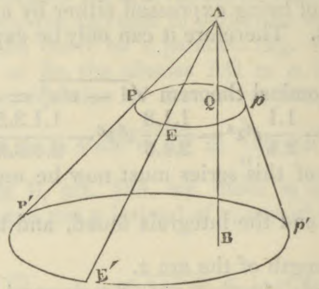
If the integral begin when $x = 0$, then also $s = 0$ and $\mathrm{C} = 0$; now πxy^2 is the content of a cylinder having the same base as the paraboloid, therefore, *a paraboloid is half a cylinder of the same base and altitude.*

From this geometrical theorem we may find the content of the solid between two sections of a paraboloid by planes perpendicular to its axis, which is called a *frustum* of a paraboloid. Let A be the area of the base of the frustum, a the area of its top, h its height, x the segment of the axis between the vertex of the paraboloid and top of the frustum. The content of the whole paraboloid $= \frac{1}{2}(x+h)\mathrm{A}$, and the content of the part cut off $= \frac{1}{2}xa$, therefore the content of the frustum $= \frac{1}{2}(x\mathrm{A} + h\mathrm{A} - xa)$. Now by the nature of the solid $\frac{x+h}{x} = \frac{\mathrm{A}}{a}$, hence $x\mathrm{A} - xa = ha$, therefore the content of the frustum is $\frac{1}{2}(\mathrm{A}+a)h$. Hence it appears that a frustum of a paraboloid is equal to a cylinder of the same altitude, and whose base is a mean between the top and bottom of the frustum.

Ex. 2. Let the solid be a cone whose vertex is A, and base P′E′p', a plane figure of any kind.

Let AB be the altitude of the cone, and PEp a section parallel to the base, meeting AB in Q. Let $b =$ the area of the base P′E′p', $v =$ area of section PEp, $c =$ AB, $x =$ AQ, $s =$ content of solid A-PEp. In this case, $ds = vdx$, an expression the same as for a solid of revolution, and found in the same way. Now, sections of similar cones are proportional to the squares of their like dimensions; therefore $c^2 : x^2 = b : v$, hence $v = \frac{bx^2}{c^2}$ and $ds = \frac{b}{c^2}x^2 dx$, and by integration $s = \frac{bx^3}{3c^2} + \mathrm{C} = \frac{vx}{3} + \mathrm{C}$. If x and s begin together, then $\mathrm{C} = 0$ and $s = \frac{1}{3}vx$. Thus it appears that *a cone of any kind is $\frac{1}{3}$ of its circumscribing cylinder.*

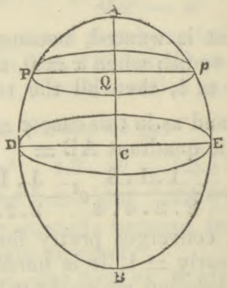
Fig. 28.



To find the content of a frustum of a cone, or space between the base and a plane parallel to its base; put $\mathrm{A} =$ area of base, $a =$ area of top, $h =$ height of frustum, $x =$ height of cone cut off above the frustum. The content of the whole cone $= \frac{1}{3}(h + x)\mathrm{A}$, and the content of the part cut off $= \frac{1}{3}xa$, therefore the content of the frustum $= \frac{1}{3}(h\mathrm{A} + x\mathrm{A} - xa) = \frac{1}{3}h\mathrm{A} + \frac{1}{3}x(\mathrm{A} - a)$. Now $\frac{\mathrm{A}}{a} = \frac{(x+h)^2}{x^2}$, and $\frac{\sqrt{\mathrm{A}}}{\sqrt{a}} = \frac{x+h}{x}$, hence $x = \frac{\sqrt{a}}{\sqrt{\mathrm{A}} - \sqrt{a}}h$, and $x(\mathrm{A} - a) = \sqrt{a}(\sqrt{\mathrm{A}} + \sqrt{a})h = (\sqrt{\mathrm{A}a} + a)h$. On the whole, the content of the frustum $= \frac{1}{3}(\mathrm{A} + a + \sqrt{\mathrm{A}a})h$.

Ex. 3. To find the content of a spheroid generated by the revolution of an ellipse about either of its axes.

Fig. 29.



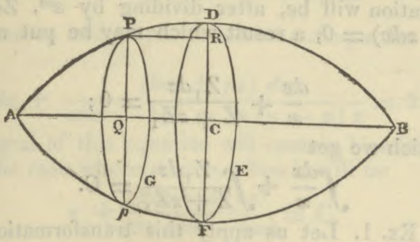
Let PQp be a section of the solid perpendicular to the fixed axis AB. Put AB $= a$, the revolving axis DE $= b$, also AQ $= x$, PQ $= y$. From the nature of the ellipse, $y^2 = \frac{b^2}{a^2}(ax - x^2)$, hence $s = \frac{\pi b^2}{a^2}\int(ax - x^2)dx = \frac{\pi b^2}{a^2}(\frac{1}{2}ax^2 - \frac{1}{3}x^3) + \mathrm{C}$.

If we suppose $s = 0$ when $x = 0$, then $\mathrm{C} = 0$. If we make $x = a$, then s, the whole spheroid, $= \frac{ab^2\pi}{6} = \frac{2}{3}a \times$ area of middle section. Hence it appears that *the whole solid is $\frac{2}{3}$ of its circumscribing cylinder.* This proposition was discovered by Archimedes.

If the axes a, b, be supposed equal, the solid is a sphere; hence it appears that the content of a sphere $= \frac{\pi}{6}a^3$, a being the diameter.

Ex. 4. Let the solid be a parabole spindle which is generated by the revolution of APB, an arc of a parabola, about ACB, an ordinate to its axis. From P any point in

Fig. 30.



the revolving curve, draw PQ perpendicular to the ordinate AB, and PR perpendicular to the axes of the parabola. Make DC $= p$, AC $= q$, CQ = PR $= x$, PQ = CR $= y$, the solid (between the sections DEF, PGp) $= s$. By the nature of the curve, $\text{PR}^2 : \text{AC}^2 = \text{DR} : \text{DC}$; that is, $x^2 : q^2 = p - y : p$; hence $p\,x^2 = pq^2 - q^2\,y$, and $y^2 = \frac{p^2}{q^4}(q^4 - 2q^2x^2 + x^4)$, and

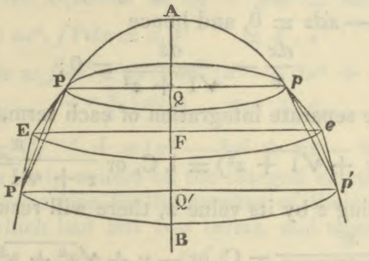
$$s = \frac{p^2\pi}{q^4}\int(q^4dx - 2q^2x^2dx + x^4dx)$$
$$= \frac{p^2\pi}{q^4}(q^4x - \tfrac{2}{3}q^2x^3 + \tfrac{1}{5}x^5) + \text{C}.$$

If the integral begin when $x = 0$, then $\text{C} = 0$. If we make $x = q$, we get $\frac{8}{15}p^2.q\pi$ for half the content of the solid generated by the curve ADB.

Surfaces of Solids.

164. Let AB be the axis of any plane curve APP′, and PQ, P′Q′ ordinates to the axis; draw PE, P′E tangents to the curve at P and P′, meeting in E; draw EF perpendicular to AB, and draw the chord PP′. Suppose now the curve to revolve about its axis AB; the arc APP′ will generate a curve surface, to be found; the portion PP′ of the arc will generate an increment of that surface, which, by an axiom in geometry, will be less than the sum of the conical surfaces generated by the tangents PE, P′E, but greater than the conical surface generated by the chord PP′. Put AQ $= x$, AQ′ $= x'$, PQ $= y$, P′Q′ $= y'$, EF $= y''$, arc AP $= z$, arc AP′ $= z'$, surface generated by arc AP $= v$, surface generated by arc AP′ $= v'$.

Fig. 31.



By the elements of geometry, the surfaces generated by the tangents PE P′E will be

$$\pi(\text{PQ} + \text{EF})\,\text{PE} = \pi(y + y'')\,\text{PE},$$
$$\pi(\text{P'Q'} + \text{EF})\,\text{P'E} = \pi(y' + y'')\,\text{P'E},$$

and the surface generated by the chord PP′ will be

$$\pi(\text{PQ} + \text{P'Q'})\,\text{PP'} = \pi(y + y')\,\text{PP'}.$$

Therefore $v' - v < \pi\{(y + y'')\,\text{PE} + (y' + y'')\,\text{P'E}\}$,

$$v' - v > \pi(y + y')\text{ chord PP'},$$

and $$\frac{v' - v}{z' - z} < \pi\frac{(y + y'')\,\text{PE} + (y' + y'')\,\text{P'E}}{\text{arc P'P}},$$

$$\frac{v' - v}{z' - z} > \pi(y + y')\frac{\text{chord P'P}}{\text{arc P'P}}.$$

Now, the point P being supposed to approach to P′, these quantities, one of which is greater than $\frac{v' - v}{z' - z}$, and the other less, become ultimately equal; for the lines y, y'', y' become equal, and $(y + y'')\,\text{PE} + (y + y'')\,\text{PE}$ becomes $(y' + y)(\text{PE} + \text{P'E})$, and the fractions $\frac{\text{PE} + \text{P'E}}{\text{arc P'P}}$, $\frac{\text{chord PP'}}{\text{arc PP'}}$ are ultimately each $= 1$; therefore,

$$\text{limit}\,\frac{v' - v}{z' - z} = 2\pi y, \text{ and } \frac{dv}{dz} = 2\pi y;$$

hence, $dv = 2\pi ydz = 2\pi y\sqrt{dx^2 + dy^2}$.

Now $2\pi y$ expresses the circumference of the section Pp; hence it appears that *the differential of the surface of revolution is equal to the differential of the arc of the generating curve multiplied by a section of the surface made by a plane perpendicular to the axis.*

165. Ex. 1. Let the solid be a sphere, of which the radius is a. Then, making AQ$=x$, PQ$=y$, the arc AP$=z$, the surface of the segment cut off by the plane P$p = v$; the equation of the curve being $y = \sqrt{2ax - x^2}$, we have

$$dy = \frac{adx - xdx}{\sqrt{2ax - x^2}},\; dz = \sqrt{dx^2 + dy^2} = \frac{adx}{\sqrt{2ax - x^2}} = \frac{adx}{y},$$

$$dv = 2\pi ydz = 2a\pi dx, \text{ and the surface } v = 2a\pi x;$$

here no constant is wanted, because we suppose that when $x = 0$, then $v = 0$.

Since $2a\pi$ is the circumference of a circle whose diameter is a, it follows that *the curve surface of a segment of a sphere is equal to a rectangle contained by a straight line equal to the circumference of the sphere and the height of the segment;* and hence it follows, that *the whole surface of the sphere is four times the area of one of its great circles.* These conclusions were found by Archimedes.

Ex. 2. To find the surface of a paraboloid. Put AQ $= x$, PQ $= y$, arc AP $= z$, curve surface generated by AP $= v$, the parameter $= 2a$. We found (article 160)

$dz = \frac{dy}{a}\sqrt{a^2 + y^2}$, hence,

$$dv = 2\pi ydz = \frac{2\pi}{a}ydy\sqrt{a^2 + y^2},$$

and, integrating, $v = \frac{2\pi}{a}\int ydy\sqrt{a^2 + y^2} = \frac{2\pi}{3a}(a^2 + y^2)^{\frac{3}{2}} + \text{C}.$

When $v = 0$, then $y = 0$; therefore, at the vertex we have

$$0 = \frac{2\pi a^3}{3a} + \text{C and C} = -\frac{2\pi a^3}{3a};$$

therefore, substituting for C, we have

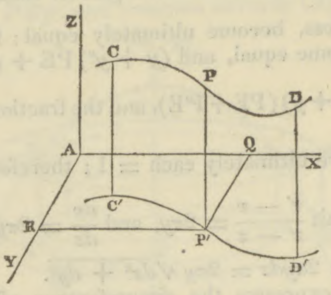
$$v = \frac{2\pi}{3a}\{(a^2 + y^2)^{\frac{3}{2}} - a^3\} = \frac{2}{3}\pi\{\sqrt{a(2x + a)^3} - a^2\}.$$

Rectification of Curves of Double Curvature.

166. Let CPD be a line of double curvature referred to three co-ordinate planes YAX, ZAX, ZAY. From every point in the curve let perpendiculars PP′, &c. be drawn to one of the planes, YAX; these will all be in the surface of a cylinder that meets the plane in a curve C′P′D, which will be the projection of the proposed curve. Again, from P′ draw P′Q, P′R perpendicular to AX, AY. Let AQ = P′R $= x$, AR = P′Q $= y$, P′P $= z$, the arc CP $= v$, its projection C′P′ $= v'$: Then $dv' = \sqrt{dx^2 + dy^2}$, (art 72). Suppose now the cylindric surface to be extended into a plane surface; the curve CPD will then be changed into a common plane curve, and its projection C′P′D′ into a straight line of the same length as before. We may now consider

Inverse Method.

Fig. 32.



v' and z as co-ordinates of the curve v, and then $dv = \sqrt{dv'^2 + dz^2}$; therefore, by substituting for dv'^2 its value $dx^2 + dy^2$, we find

$$dv = \sqrt{dx^2 + dy^2 + dz^2}.$$

This is a general formula for the rectification of any line of double curvature. The nature of the line will be expressed by two equations $f(x, y) = 0$, $\mathrm{F}(x, z) = 0$. From these we find $dy = \mathrm{P}dx$, $dz = \mathrm{Q}dx$, expressions in which P and Q are functions of x only. Thus we have $dv = dx\sqrt{1 + \mathrm{P}^2 + \mathrm{Q}^2} = dx\mathrm{R}$, R being a function of the single variable x. The integral $v = \int \mathrm{R}dx$ may now be found by the ordinary rules.

Integration of Differential Equations of two Variables.

167. Every differential equation of the first order which contains only the single powers of dx and dy, has the form $\mathrm{M}dx + \mathrm{N}dy = 0$, and it expresses the relation which subsists between the variable x, the function y, and its differential co-efficient $\frac{dy}{dx}$. The object of inquiry is to discover, if possible, the primitive equation $f(x, y) = 0$, which by differentiation may produce the proposed differential equation.

168. The method which first presented itself to analysts was to endeavour to separate the variables, so as to give it the form $\mathrm{X}dx + \mathrm{Y}dy = 0$, X being a function of x alone, and Y a function of y. When this can be done, the differentials $\mathrm{X}dx$, $\mathrm{Y}dy$ are separately integrable, and we have $\int \mathrm{X}dx + \int \mathrm{Y}dy = \mathrm{C}$ an arbitrary constant.

Let the equation be $mydx + nxdy = 0$; by dividing its terms by xy, it is changed to $\frac{mdx}{x} + \frac{ndy}{y} = 0$. The variables are now separated, and we have $\int \frac{mdx}{x} + \int \frac{ndy}{y} = m\,\mathrm{l}.\,x + n\,\mathrm{l}.\,y = \mathrm{C}$, or $\mathrm{l}.\,(x^m) + \mathrm{l}.\,(y^n) = \mathrm{C}$, or $\mathrm{l}.\,(x^m y^n) = \mathrm{C}$. We may suppose $\mathrm{C} = \mathrm{l}.\,c$, and then $x^m y^n = c$ is the primitive equation.

The variables may be separated when the differential equation has the form $\mathrm{X}dy + \mathrm{Y}dx = 0$, X being a function of x, and Y a function of y; for then $\frac{dx}{\mathrm{X}} + \frac{dy}{\mathrm{Y}} = 0$.

169. The variables may always be separated in *homogeneous equations*, the distinguishing property of which is, that the sum of the exponents of x and y is the same in each of its terms. For example, $ax^m y^n dx + bx^{m-1} y^{n+1} dy$ is a homogeneous equation; because the sum of the exponents of x and y is $m + n$ in each term. Let $\mathrm{M}dx + \mathrm{N}dy = 0$ be a homogeneous equation. Make $y = xz$, then M will take the form $\mathrm{Z}x^m$, and N the form $\mathrm{Z}_1 x^m$, Z and Z_1 being functions of z only; and since $dy = zdx + xdz$, the equation will be, after dividing by x^m, $\mathrm{Z}dx + \mathrm{Z}_1(xdz + zdx) = 0$, a result which may be put under the form

$$\frac{dx}{x} + \frac{\mathrm{Z}_1 dz}{\mathrm{Z} + z\mathrm{Z}_1} = 0;$$

from which we get

$$\int \frac{dx}{x} + \int \frac{\mathrm{Z}_1 dz}{\mathrm{Z} + z\mathrm{Z}_1} = \mathrm{C}.$$

170. Ex. 1. Let us apply this transformation to the equation $xdx + ydy = nydx$ or $(x - ny)\,dx + ydy = 0$, which, making $y = xz$, and therefore $dy = xdz + zdx$, becomes $x(1 - nz)\,dx + x^2zdz + xz^2dx = 0$, or $(1 - nz + z^2)\,dx + zdz = 0$, and $\int \frac{dx}{x} + \int \frac{zdz}{1 - nz + z^2} = \mathrm{C}$, or $\mathrm{l}.\,x + \int \frac{zdz}{1 - nz + z^2} = \mathrm{C}$. This integral may be simplified by observing that

$$\frac{zdz}{1 - nz + z^2} = \tfrac{1}{2}\,\frac{2zdz - ndz}{1 - nz + z^2} + \tfrac{1}{2}\,\frac{ndz}{1 - nz + z^2},$$

for it then becomes

$$\mathrm{l}.\,x + \tfrac{1}{2}\,\mathrm{l}.\,(1 - nz + z^2) + \tfrac{1}{2}\int \frac{ndz}{1 - nz + z^2} = \mathrm{C}.$$

The integral which yet remains to be found will depend on logarithms, if $\frac{1}{2}n > 1$; on arcs of circles, if $\frac{1}{2}n < 1$; and will be algebraical if $\frac{1}{2}n = 1$. In each case it may be had by the methods given for integrating rational fractions.

Ex. 2. Let it be proposed to integrate the equation

$$xdy - ydx = dx\sqrt{x^2 + x^2}.$$

By making $y = xz$, bringing all the terms to one side of the equation, and dividing by x, we shall have $dx\sqrt{1 + z^2} - xdz = 0$, and hence

$$\frac{dx}{x} - \frac{dz}{\sqrt{1 + z^2}} = 0;$$

and by the separate integration of each term,

$$\mathrm{l}.\,x - \mathrm{l}.\,(z + \sqrt{1 + z^2}) = \mathrm{l}.\,\mathrm{C}, \text{ or } \frac{x}{z + \sqrt{1 + z^2}} = \mathrm{C}.$$

and replacing z by its value x, there will result

$$\frac{x^2}{y + \sqrt{x^2 + y^2}} = \mathrm{C}, \text{ or } -y + \sqrt{x^2 + y^2} = \mathrm{C};$$

and hence again, by transposing y, and squaring, $x^2 = \mathrm{C}^2 + 2\mathrm{C}y$, which is the primitive equation.

The equation

$$(a + mx + ny)\,dx + (b + px + qy)\,dy = 0,$$

which is not homogeneous in its present form, may be transformed so as to become homogeneous. Assume $x = t + \alpha$, $y = u + \beta$, then $dx = dt$, $dy = du$, and the proposed equation becomes
$(a + m\alpha + n\beta + mt + nu)dt + (b + p\alpha + q\beta + pt + qu)du = 0.$
To make the constant terms disappear, we assume $a + m\alpha + n\beta = 0$, $b + p\alpha + q\beta = 0$, equations which determine α and β, and then there remains the different equation

$$(mt + nu)\,dt + (pt + qu)\,du = 0,$$

which is homogeneous in respect of the new variables t and u. This transformation gives no result when $mq - np = 0$, a case in which α and β become infinite; but then $q = \frac{np}{m}$; and consequently $m(px + qy) = p(mx + ny)$. The proposed equation being changed to

$$adx + bdy + (mx + ny)\left(dx + \frac{p}{m}dy\right) = 0,$$

we now make $mx + ny = z$, so that $dy = \frac{dz - mdx}{n}$; by substitution and proper reduction our equation now becomes

$$dx + \frac{(bm + pz)\,dz}{amn - bm^2 + m\,(n - p)\,z} = 0.$$

The integral of this equation will contain logarithms, except in the case where $n = p$, when it will be

$$x + \frac{2bmz + pz^2}{2m\,(an - bm)} = \mathrm{C}.$$

171. The separation of the variables is easily effected in the equation $dy + \mathrm{P}ydx = \mathrm{Q}dx$, where P and Q denote any functions whatever of x. Substituting $\mathrm{X}z$ and $zd\mathrm{X} + \mathrm{X}dz$ instead of y and dy, it becomes

$$zd\mathrm{X} + \mathrm{X}dz + \mathrm{PX}zdx = \mathrm{Q}dx.$$

Here X denotes an indeterminate function of x, to which we may give such a form as shall conduce to the separation of the variables. For this purpose we make $\mathrm{X}dz + \mathrm{PX}zdx = 0$, which requires that $zd\mathrm{X} = \mathrm{Q}dx$. If we divide the first equation by X, it becomes $dz + \mathrm{P}zdx = 0$, from which we deduce $\frac{dz}{z} + \mathrm{P}dx = 0$, and $\mathrm{l}.\,z + \int \mathrm{P}x = 0$; and passing from logarithms to numbers, $z = e^{-\int \mathrm{P}dx}$ (here e is the base of Napier's logarithms), we neglect the arbitrary constant in the mean time, as it will be added at the end of the operation. Afterwards, deducing the value of $d\mathrm{X}$ from the second equation, and substituting it in the first, we shall have

$$d\mathrm{X} = e^{\int \mathrm{P}dx}\,\mathrm{Q}dx,\ \mathrm{X} = \int e^{\int \mathrm{P}dx}\,\mathrm{Q}dx + \mathrm{C},$$

and consequently,

$$y = e^{-\int \mathrm{P}dx}\{\int e^{\int \mathrm{P}x}\,\mathrm{Q}dx + \mathrm{C}\}$$

Ex. Let the equation be $dy + ydx = ax^3\,dx$: then $\mathrm{P} = 1, \mathrm{Q} = ax^3, \int \mathrm{P}dx = x, e^{\int \mathrm{P}dx} = e^x, e^{-\int \mathrm{P}dx} = e^{-x}$; $\int e^{\int \mathrm{P}dx}\,\mathrm{Q}dx = \int ae^x\,x^3dx = ae^x\,(x^3 - 3x^2 + 6x - 6)$; therefore $y = e^{-x}\,\{ae^x(x^3 - 3x^2 + 6x - 6) + \mathrm{C}\}$

$$= \mathrm{C}e^{-x} + a\,(x^3 - 3x^2 + 6x - 6).$$

172. The early writers on the integral calculus classed differential equations by the number of their terms. In equations which had but two terms, and whose form is consequently $\beta u^g z^h dz = \alpha u^e z^f du$, the variables are separated immediately, since we thence deduce $\beta z^{h-f} dz = \alpha u^{e-g} du$. This however is not the case with equations of three terms, which are expressed by the formula

$$\gamma u^i z^k\,dz + \beta u^g z^h\,du = \alpha u^e z^f du.$$

This may be simplified by dividing the terms by $\gamma u^i z^f$, it then becomes

$$z^{k-f} dz + \frac{\beta}{\gamma} u^{g-i} z^{h-f} du = \frac{\alpha}{\gamma} u^{e-i}\,du.$$

Suppose now $z^{k-f} dz = \frac{dy}{k - f + 1}$, $u^{g-i} du = \frac{dx}{g - i + 1}$; then we have $z^{k-f+1} = y$, $u^{g-i+1} = x$, and

$$dy + \frac{(k - f + 1)\beta}{(g - i + 1)\gamma}\,y^{\frac{k-f}{k-f+1}}\,dx = \frac{(k - f + 1)\alpha}{(g - i + 1)\beta}\,x^{\frac{e-g}{g-i+1}}\,dx.$$

To abridge, let us put

$$b = \frac{(k - f + 1)\,\beta}{(g - i + 1)\,\gamma},\quad a = \frac{(k - f + 1)\,\alpha}{(g - i + 1)\,\gamma},$$

$$n = \frac{h - f}{k - f + 1},\quad m = \frac{e - g}{g - i + 1};$$

and the equation will become

$$dy + by^n dx = ax^m dx.$$

When $n = 1$, the equation belongs to the class treated of in last article. When $n = 2$, the equation is

$$dy + by^2 dx = ax^m dx,$$

which was first considered by an Italian geometer, *Riccati*, whose name it bears. When $m = 0$, the variables are separable, and we have

$$dx = \frac{dy}{a - by^2}.$$

Proceeding from this case, analysts have succeeded in separating the variables when m is any number of the form $\frac{-4i}{2i \pm 1}$, i being supposed an integer number. Riccati's equation was first considered by James Bernoulli, who gave an approximate solution of it. (Jac. Bernoulli *Opera*, p. 1053.) The general problem, however, remains yet unresolved.

173. When a differential equation is the immediate result of the differentiation of a known function, then that function, put equal to C a constant, will be the integral required. The differential equation $xdy + ydx = 0$ is of this class; it is the differential of the product xy, therefore the primitive equation is $xy = \mathrm{C}$. A differential equation may, however, not be the immediate result of the differentiation of a function of x and y; it may be formed by the elimination of some constant quantity contained in the function and also in its differential (art. 54); or it may be the result after the differential of the primitive has been divided by some factor common to all its terms. Thus, if the primitive be $y = cx$, or $y - cx = 0$, the differential equation is $dy - cdx = 0$. If however we eliminate c by the usual algebraic process, we find $xdy - ydx = 0$, an expression which is not the immediate result of any differentiation. The same result will be obtained if the primitive $x = cy$ be put under the form $\frac{x}{y} = c$; for then, by differentiating, $\frac{ydx - xdy}{y^2} = 0$, and, rejecting the factor $\frac{1}{y^2}$, $ydx - xdy = 0$. This expression is not an exact differential; however, it becomes so by restoring the factor $\frac{1}{y^2}$, and then it is the differential of $\frac{x}{y}$.

174. In general let $u = f(x, y)$ be the primitive equation, the differential being $du = \mathrm{M}dx + \mathrm{N}dy$, where M denotes $\frac{du}{dx}$, that is, the differential co-efficient found on the supposition that x is variable and y constant, and N denotes $\frac{du}{dy}$, the co-efficient taken on the reverse hypothesis of y being variable and x constant; now we have found that $\frac{d^2u}{dxdy} = \frac{d^2u}{dydx}$ (art. 89); therefore, if $\mathrm{M}dx + \mathrm{N}dy$ be the differential of $u = f(x, y)$, then

$$\frac{d\mathrm{M}}{dy} = \frac{d\mathrm{N}}{dx} \ldots\ldots\ldots\ldots\ldots\ldots\ldots(1)$$

Hence, *If* Mdx + Ndy *is an exact differential, the condition expressed by formula* (1) *will always be satisfied. And, conversely, if* M *and* N *are such functions of* x *and* y *that* $\frac{\mathrm{dM}}{\mathrm{dy}} = \frac{\mathrm{dN}}{\mathrm{dx}}$, *then* Mdx + Ndy *shall be an exact differential, and in every case its integral may be found.* This is called the *Condition of Integrability.*

To prove the second part of the proposition, let us suppose that the integral of Mdx is taken on the supposition that in the function M, x is variable and y constant; and let the integral be $P+Y$, where Y is any function of y, which comes in the place of the indeterminate constant that enters into every integral, and P is a known function of x and y, which results from $\int Mdx$ relatively to x only, so that $M=\frac{dP}{dx}$.

The complete differential of $P+Y$ is (art. 91) $\frac{dP}{dx}dx+\frac{dP}{dy}dy+dY$, or $Mdx+\frac{dP}{dy}dy+dY$. By comparing this with the differential $Mdx+Ndy$, it appears that if such a value be given to Y that $Ndy=\frac{dP}{dy}dy+dY$, or that

$$dY=\left(N-\frac{dP}{dy}\right)dy\ldots\ldots\ldots\ldots(2)$$

then the integral of $Mdx+Ndy$ will be $P+Y$. Now, by differentiating $M=\frac{dP}{dx}$ in respect of y, we have $\frac{dM}{dy}=\frac{d^2P}{dydx}$, but by hypothesis $\frac{dM}{dy}=\frac{dN}{dx}$, and $\frac{d^2P}{dydx}=\frac{d^2P}{dxdy}$ (art. 89), therefore $\frac{dN}{dx}=\frac{d^2P}{dxdy}$, and $\frac{dN}{dx}-\frac{d^2P}{dxdy}=0$, that is, $d\left(N-\frac{dP}{dy}\right)=0$, the differential being taken supposing x only to be variable; therefore $N-\frac{dP}{dy}$ is constant in respect of x, and is a function of y only; hence the possibility of finding $Y=\int\left(N-\frac{dP}{dy}\right)dy$ is proved, and we have the integral of $Mdx+Ndy$ expressed by $P+\int\left(N-\frac{dP}{dy}\right)dy$, and here $P=\int Mdx$, the integral being taken on the supposition that y is constant.

We may begin with finding the integral of Ndy, supposing x to be constant, proceeding in all respects as has been explained. In general we ought to begin with the term which brings out the integral with least calculation.

Ex. 1. It is proposed to find whether the differential $\frac{ydx-xdy}{x^2+y^2}$ satisfies the condition of integrability, and, if it does, to integrate it.

We put the differential under the form

$$du=\frac{y}{x^2+y^2}dx-\frac{x}{x^2+y^2}dy,$$

therefore $M=\frac{y}{x^2+y^2}$, $\quad N=-\frac{x}{x^2+y^2}$,

$$\frac{dM}{dy}=\frac{x^2-y^2}{(x^2+y^2)^2},\quad \frac{dN}{dx}=\frac{x^2-y^2}{(x^2+y^2)^2}.$$

The condition of integrability is in this case satisfied, and therefore $\frac{ydx-xdy}{x^2+y^2}$ is an exact differential.

To determine the integral, we have

$$P=\int Mdx=\int\frac{ydx}{x^2+y^2}=\int\frac{\frac{dx}{y}}{1+\frac{x^2}{y^2}}=\tan^{-1}\frac{x}{y},$$

whence $u=\tan^{-1}\frac{x}{y}+Y$.

Differentiating, and considering the whole as variable,

$$du=\frac{ydx-xdy}{x^2+y^2}+dY.$$

This, compared with the proposed differential, shows that $dY=0$, and $Y=C$ a constant.

Ex. 2. To find the integral of the differential

$$du=(2y^2x+3y^3)\,dx+(2x^2y+9xy^2+8y^3)\,dy.$$

In this example, $M=2y^2x+3y^3$, $N=2x^2y+9xy^2+8y^3$,

$$\frac{dM}{dy}=4yx+9y^2=\frac{dN}{dx};$$

the proposed function is therefore a complete differential.

Integrating in respect of x, we find

$$\int Mdx=y^2x^2+3y^3x+Y,$$

and $u=y^2x^2+3y^3x+Y$.

Differentiating this expression in respect of y,

$$\frac{du}{dy}=2x^2y+9xy^2+\frac{dY}{dy},$$

but we had $\frac{du}{dy}=2x^2y+9xy^2+8y^3$;

therefore, $\frac{dY}{dy}=8y^3$, and $Y=\int 8y^3dy=2y^4+C$,

and consequently the integral is

$$u=y^2x^2+3y^3x+2y^4+C.$$

175. If in the equation $Mdx+Ndy=0$, the condition of integrability, viz. $\frac{dM}{dy}=\frac{dN}{dx}$, is not satisfied, we may next inquire whether some factor, a function of x and y, can be found by which the expression $Mdx+Ndy$ can be rendered a complete differential.

Let the equation be put under the form $\frac{dy}{dx}+K=0$, where $K=\frac{M}{N}$. This equation is the result of the elimination of a constant quantity c between a primitive equation, which may be represented by $f(x,y,c)=0$ and its immediate differential. Or else c may be eliminated directly by bringing the primitive equation to the form $F(x,y)=c$, which will lead to the same result (art 53). Put u for $F(x,y)$, also Pdx for the differential of u taken relatively to x, and Qdy for its differential relatively to y, so that $du=Pdx+Qdy$, and $\frac{du}{dx}=P+Q\frac{dy}{dx}=0$, therefore $P+Q\frac{dy}{dx}=0$. Since this equation does not contain C, it ought to be identical with the equation $\frac{dy}{dx}+K=0$;

therefore $\frac{dy}{dx}+K=\frac{dy}{dx}+\frac{P}{Q}=\frac{Pdx+Qdy}{Qdx}$, that is, $\frac{dy}{dx}+K=\frac{du}{Qdx}$, and hence

$$Q(dy+Kdx)=du.$$

Now the second side of the equation is a complete integral; hence it appears that *there is always a factor* Q, *by which, if the differential equation* $dy+Kdx=0$ *be multiplied, the result will be a complete integral.*

Let both sides of the equation be multiplied by U, any function of U, and we have

$$UQ(dy+Kdx)=Udu.$$

Now Udu is still a complete differential, and as the factor UQ may have an infinite variety of forms, it follows that *there are an infinite number of factors, such that if a differential equation be multiplied by any one of them, it will be a complete differential.*

Inverse Method.

Since it appears that when the equation $\text{M}dx+\text{N}dy=0$ does not satisfy the condition of integrability, it is because differentiation and subsequent elimination of the arbitrary constant have caused a factor to disappear, which, if it were known and restored, would render the expression a complete differential, the discovery of that factor is a most important problem in the calculus. Its solution, however, transcends the present powers of analysis, although it can be resolved in particular cases. When the functions M and N are homogeneous, the factor can be found; but that case can always be integrated as has been explained. When the variables can be separated, a multiplier can be found, but then it is not wanted. It can also be found when the equation has the form $dy+\text{P}ydx=\text{Q}dx$; but this also can be integrated by other means.

Euler, who has entered deeply into this subject, has reversed the problem; and, in his *Calculus Integralis*, supposing the integrating factor given, has investigated the nature of the functions which must enter into a differential equation of a given form, in order that it may be integrable. These investigations, however, frequently lead to differential equations, which cannot be integrated by any known method; and the cases in which they are successful are of no great importance or extent.

176. Let M be any function of x and y, and let $u=\int\text{M}dx$, the integral being taken on the supposition that x is variable and y constant: it is sometimes required that the differential co-efficient $\frac{du}{dy}$ be found; or, in other words, that the differential of $\int\text{M}dx$ relatively to y be found without having actually integrated the expression relatively to x. Because $u=\int\text{M}dx$, therefore $\frac{du}{dx}=\text{M}$, and $\frac{d^2u}{dxdy}=\frac{d\text{M}}{dy}$; but $\frac{d^2u}{dxdy}=\frac{d^2u}{dydx}$ (art. 89), therefore $\frac{d^2u}{dydx}=\frac{d\text{M}}{dy}$, and $\frac{d^2u}{dy}=\frac{d\text{M}}{dy}dx$, and integrating relatively to x, $\frac{du}{dy}=\int\frac{d\text{M}}{dy}dx$.

Ex. Let $u=\int\frac{ydx}{\sqrt{y^2-x^2}}$, here $\text{M}=\frac{y}{\sqrt{y^2-x^2}}$, and $\frac{d\text{M}}{dy}=\frac{-x^2}{(y^2-x^2)^{\frac{3}{2}}}$, and $\frac{du}{dx}=\int\frac{-x^2dx}{(y^2-x^2)^{\frac{3}{2}}}$.

The theorem investigated in this article was found by Leibnitz, and was reckoned an important discovery in the calculus. (See Bossut, *Traité du Calcul Diff.* &c. vol. ii. p. 58.)

177. The elimination of a constant contained in a primitive equation may introduce the second or higher powers of the differentials into the resulting differential equation (art. 53): in such cases we must find the values of $\frac{dy}{dx}$ by the resolution of an equation.

For example, if $dy^2-a^2dx^2=0$, or $\frac{dy^2}{dx^2}=a^2$, we have $\frac{dy}{dx}=\pm a$ and $dy+adx=0$, also $dy-adx=0$; therefore $y+ax+c=0$ and $y-ax+c'=0$ are two primitive equations, from each of which the differential equation may be derived; also from their product $(y+ax+c)(y-ax+c')=0$.

178. When the equation contains only one of the variables, x for example, we deduce from it $\frac{dy}{dx}=\text{X}$, and $y=\int\text{X}dx$; but if the equation be more easily resolvable with respect to x than with respect to the co-efficient $\frac{dy}{dx}$, which we will represent by p, and if we have also $x=\text{P}$, a function of p, and thence $dx=d\text{P}$; then, since $dy=pdx$, therefore $dy=pd\text{P}$, and $y=p\text{P}-\int\text{P}dp$. The relation between x and y is now to be found by eliminating p by means of the equations

$$x=\text{P},\quad y=\text{P}p-\int\text{P}dp.$$

Let us take as an example $xdx+ady=b\sqrt{dx^2+dy^2}$, or $x+ap=b\sqrt{1+p^2}$, by writing p in the place of $\frac{dy}{dx}$. This last equation gives immediately $x=-ap+b\sqrt{1+p^2}$, and consequently

$$y=bp\sqrt{1+p^2}-\tfrac{1}{2}ap^2-b\int dp\sqrt{1+p^2}.$$

179. When the primitive equation cannot be deduced from the differential equation by any of the known artifices of analysis, then, as a last resource, recourse must be had to approximation by infinite series.

Ex. Let the differential equation be $dy+ydx=mx^ndx$, and suppose it to be known that when $x=a$, then $y=b$: we now make $x=a+t$, $y=b+u$, the equation by this transformation becomes $du+(b+u)dt=m(a+t)^ndt$. We now assume that

$$u=\text{A}t^\alpha+\text{B}t^{\alpha+1}+\text{C}t^{\alpha+2}+\&\text{c.}$$

and hence, putting instead of u and du their values, and bringing the terms to one side, we have

$$\left.\begin{array}{l}\alpha\text{A}t^{\alpha-1}+(\alpha+1)\text{B}t^\alpha+(\alpha+2)\text{C}t^{\alpha+1}+\&\text{c.}\\ +b\quad+\quad\text{A}t^\alpha\quad+\quad\text{B}t^{\alpha+1}+\&\text{c.}\\ -ma^n-m\frac{n}{1}a^{n-1}t-m\frac{n(n-1)}{1.2}a^{n-2}t^2-\&\text{c.}\end{array}\right\}=0.$$

In this equation we must suppose $\alpha-1=0$, and we shall then find

$$\text{A}=ma^{n-1}-b,\ \text{B}=\frac{mna^{n-1}-ma^n+b}{1.2},$$

$$\text{C}'=\frac{mn(n-1)a^{n-2}-mna^{n-1}+ma^n-b}{1.2.3},\ \&\text{c.}$$

These values being substituted in the series, we have u expressed by t and known quantities; we may then put $x-a$ for t, and $y-b$ for u, and the result will express the relation between x and y.

In the series assumed for the value of u, the exponents of t form an arithmetical progression, of which the common difference is 1. In many cases, however, the common difference will be a fraction, as in this example, $(dx+dy)\,y=dx$. Here we assume

$$y=\text{A}x^a+\text{B}x^b+\text{C}x^c+\&\text{c.}$$

By proceeding as before, there is obtained

$$\left.\begin{array}{l}\text{A}^2ax^{2a-1}+\text{AB}ax^{a+b-1}+\text{AC}ax^{a+c-1}+\&\text{c.}\\ \qquad\qquad+\text{AB}bx^{a+b-1}+\text{B}^2bx^{2b-1}+\&\text{c.}\\ \qquad\qquad\qquad\qquad+\text{AC}cx^{a+c-1}+\&\text{c.}\\ \qquad\qquad\qquad\qquad\qquad\qquad+\&\text{c.}\\ -1\quad+\text{A}x^a\quad+\text{B}x^b\end{array}\right\}=0.$$

Hence $2a-1=0$, $a+b-1=a$, $a+c-1=b$, &c.;

therefore $a=\frac{1}{2}$, $b=1$, $c=\frac{3}{2}$, &c.

Again, $\text{A}^2a=1$, $\text{AB}(a+b)+\text{A}=0$, &c.

Hence $\text{A}=\sqrt{2}$, $\text{B}=-\frac{2}{3}$, $\text{C}=\frac{1}{18}\sqrt{2}$, &c.

and $y=x^{\frac{1}{2}}\sqrt{2}-\frac{2}{3}x^{\frac{2}{2}}+\frac{1}{18}x^{\frac{3}{2}}\sqrt{2}-\&\text{c.}$

On the integration of differential equations by series, consult Euler, *Instit. Cal. Integ.* vol. i. sect. 2; Lacroix, *du Calcul Diff.* part ii. chap. 6.

Differential Equations of the Second and Higher Orders.

180. The difficulty of the integrations becomes so much the greater the higher the order of the differential co-efficients which they involve, and we only succeed in effecting it in a very small number of very limited equations.

Let the expression

$$f(x,\ y,\ c,\ c') = 0 \ldots\ldots\ldots\ldots\ldots\ldots\ldots (1)$$

represent any primitive equation composed of the variables x, y, and two constant quantities c, c', besides any other constants. By differentiation (as explained art. 48–54), there is formed its differential equation of the first order, which will contain $\frac{dy}{dx}$. Let this differential co-efficient be represented by p, and let $q = \frac{dp}{dx} = \frac{d^2y}{dx}$. The differential of the first order will contain x, y, p, c, c', and may be represented by

$$f'(x,\ y,\ p,\ c,\ c') = 0 \ldots\ldots\ldots\ldots\ldots\ldots (2)$$

By differentiating this equation we obtain another which contains also $\frac{d^2y}{dx^2} = q$, and may be expressed by

$$f''(x, y, p, q, c, c') = 0 \ldots\ldots\ldots\ldots\ldots (3)$$

Since these three equations must hold true at once, we may eliminate the constants c, c', and the result will be a single equation,

$$\mathrm{F}(x, y, p, q) = 0 \ldots\ldots\ldots\ldots\ldots\ldots\ldots (4)$$

in which c, c' are not found. This will be the differential equation of the second order, deducible from the primitive (1), and which is independent of the constants c, c'.

We may arrive at the very same equation (4) in two other ways. We may give the primitive (1) these forms:

$$\varphi(x, y, c) = c', \quad \psi(x, y, c') = c,$$

from which, by differentiation, two results will be obtained, one entirely free from c', and the other from c: these again may have the forms

$$\varphi'(x, y, p) = c, \quad \psi'(x, y, p) = c'.$$

By taking now the differentials of these equations, we shall obtain the very same equation from each, which will be identical with equation (4).

For example, let the primitive equation be

$$x^2 - 2ax + 2by = 0,$$

in which a and b represent the constants c, c'; by differentiation, we find

$$x - a + b\frac{dy}{dx} = 0, \quad 1 + b\frac{d^2y}{dx^2} = 0.$$

After eliminating a and b by the three equations, we have this differential equation,

$$2y - 2x\frac{dy}{dx} + x^2\frac{d^2y}{dx^2} = 0.$$

We may otherwise put the primitive equation under these forms:

$$\frac{x^2 + 2by}{x} = 2a, \quad \frac{x^2 - 2ax}{y} = -2b.$$

Taking now the differentials, and arranging the results so that the constants may stand alone, and putting p instead of $\frac{dy}{dx}$, we have

$$\frac{x^2}{y - xp} = 2b, \quad \frac{2xy - x^2p}{y - xp} = 2a.$$

By differentiating either of these, the constants disappear, and in each case the result is the same, viz.

$$2y - 2x\frac{dy}{dx} + x^2\frac{d^2y}{dx^2} = 0.$$

181. Since two of the constants in a primitive equation may not be found in the differential equation of the second order derived from it, so, reversely, in returning from a differential equation of the second order to its absolute primitive, *the latter cannot be complete unless it contain two arbitrary constants, which are not in the former;* and as the same differential equation of the second order may be obtained from two distinct differential equations of the first order, it follows that *every differential equation of the second order has two distinct differential equations of the first order, each having its own arbitrary constant; and these again have one and the same absolute primitive equation.* The properties of differential equations of the third and higher orders are perfectly analogous to these.

182. The most simple differential equation of the second order is $\frac{d^2y}{dx^2} = \mathrm{X}$, a function of x; then $\frac{dy}{dx} = \int \mathrm{X}dx$. Let P be the variable part of the integral $\int \mathrm{X}dx$, and c the constant, so that $\frac{dy}{dx} = \mathrm{P} + c$; hence again $dy = \mathrm{P}dx + cdx$, and by a second integration, $y = \int \mathrm{P}dx + cx + c'$. Since $\int \mathrm{P}dx = \mathrm{P}x - \int x d\mathrm{P} = x\int \mathrm{X}dx - \int x\mathrm{X}dx$, therefore,

$$y = x\int \mathrm{X}dx - \int x\mathrm{X}dx + cx + c'.$$

The primitive of the differential equation $d^3y - \mathrm{X}dx^3 = 0$ may be found in the same way. We first put it under the form $\frac{d^3y}{dx^2} = \mathrm{X}dx$; then we have by a first integration $\frac{d^2y}{dx^2} = \int \mathrm{X}dx = \mathrm{P} + c$; and hence $\frac{d^2y}{dx} = \mathrm{P}dx + cdx$; by a second integration, $\frac{dy}{dx} = \int \mathrm{P}dx + cx + c' = \mathrm{P}' + cx + c$; here $\mathrm{P}' = \int \mathrm{P}dx$. We have now $dy = \mathrm{P}'dx + cxdx + c'dx$; and lastly, $y = \int \mathrm{P}'dx + \frac{1}{2}cx^2 + c'x + c''$. The primitive thus containing three arbitrary constants: a like differential equation of the fourth order would contain four, and so on.

183. When a differential equation of the second order involves $\frac{dy}{dx}$ and $\frac{d^2y}{dx^2}$, and constants; if we put $\frac{dy}{dx} = p$, then, regarding dx as constant, $\frac{d^2y}{dx^2} = \frac{dp}{dx}$; the equation will now involve p, dp, dx and constants; and it will be of the first order, in respect of p and x. We may thence find $dx = \mathrm{P}dp$, P being here put for some function of p; and since $dy = pdx = \mathrm{P}pdp$, we have

$$x = \int \mathrm{P}dp, \quad y = \int \mathrm{P}pdp.$$

These integrals being found, and a constant added to each, by eliminating p, we find an equation expressing the relation between x and y.

Ex. To integrate the equation $\frac{(dx^2 + dy^2)^{\frac{3}{2}}}{dxd^2y} = a$. By putting pdx for dy, and $dpdx$ for d^2y, the equation is changed to $\frac{(1+p^2)^{\frac{3}{2}}dx}{dp} = a$, from which we deduce

$$dx = \frac{adp}{(1 + p^2)^{\frac{3}{2}}}, \quad dy = pdx = \frac{apdp}{(1 + p^2)^{\frac{3}{2}}}.$$

The integration gives

$$x = c + \frac{ap}{\sqrt{1 + p^2}}, \quad y = c' - \frac{a}{\sqrt{1 + p^2}}.$$

Hence $(c - x)^2 + (y - c')^2 = a^2$.

The proposed differential equation is nothing more than the general expression of the radius of curvature (art. 78) made equal to a constant quantity a. We have resolved the geometrical problem, to find a curve whose radius of curvature is a constant, and found it to be a circle, as was obvious.

184. We may remark, that the equation $x = C + \int \frac{dp}{P}$, and $dy = C' + \int \frac{pdp}{P}$, severally satisfy the differential equation $\frac{dp}{dx} = P$; and that, by supposing their second members integrated, they will be only of the first order. This agrees with what was observed, art. 181, viz. that there are two equations of the first order which satisfy a differential equation of the second order.

185. Let us now consider differentials of the form $\frac{d^2y}{dx^2} = Y$, Y representing any function of y. If we make $dy = pdx$, we thence deduce $dx = \frac{dy}{p}$, which gives $\frac{d^2y}{dx^2} = \frac{dp}{dx} = \frac{pdp}{dy}$. Substituting this in the proposed equation, there results from it $pdp = Ydy$; by integrating, we find $p^2 = 2\int Ydy$, C, and hence

$$p = \frac{dy}{dx} = \sqrt{C + 2\int Ydy}, \text{ and } x = \int \frac{dy}{\sqrt{C + 2\int Y dy}} + C'.$$

It is proper to observe that the above integration may be effected by multiplying the proposed equation by dy, for thence we find $\frac{dy}{dx} \cdot \frac{d^2y}{dx} = Ydy$; and since $\frac{d^2y}{dx} = d\frac{dy}{dx}$, we have $\frac{1}{2}\frac{dy^2}{dx^2} = \int Ydy + C$, or $\frac{dy}{dx} = \sqrt{2\,C + 2\int Ydy}$.

Ex. Let the equation be $d^2y\sqrt{ay} = dx^2$; we shall have

$$\frac{d^2y}{dx^2} = \frac{1}{\sqrt{ay}}, \quad \frac{dy}{dx} \cdot \frac{d^2y}{dx} = \frac{dy}{\sqrt{ay}},$$

and, by integrating, $\frac{1}{2}\frac{dy^2}{dx^2} = \frac{2}{a}\sqrt{ay} + C$; changing C into $\frac{2c}{\sqrt{a}}$, we shall deduce from thence

$$\frac{dy^2}{dx^2} = \frac{4}{\sqrt{a}}(\sqrt{y} + c), \quad \frac{2dx}{\sqrt[4]{a}} = \frac{dy}{\sqrt{c + \sqrt{y}}}.$$

Now, making $c + \sqrt{y} = z$, there will result

$$\frac{dx}{\sqrt[4]{a}} = \frac{(z - c)}{\sqrt{z}}\, dz = (z^{\frac{1}{2}} - cz^{-\frac{1}{2}})dz;$$

and finally,

$$\frac{x}{\sqrt[4]{a}} = \tfrac{2}{3} z^{\frac{3}{2}} - 2cz^{\frac{1}{2}} + c' = \tfrac{2}{3}(\sqrt{y} - 2c)\sqrt{c + \sqrt{y}}. + c'.$$

186. We have seen in the differential calculus, art. 93, that beyond the first order the form of the differential equations would be changed, according as x or y, or even a function of these quantities, was assumed as the *independent variable*; which comes to the same thing as assuming that dx, or dy, or a given function of these variables, was constant. It is therefore necessary, in integrating equations which exceed the first degree, to know upon which of these hypotheses it has been calculated. The preceding examples all correspond to the case of y being a function of x, and consequently of dx being constant; but it will be easy to discover, among relations deduced relatively to other hypotheses, to which of them they may be referred.

It is immediately evident that, if we represent by Q any function whatever of $\frac{dx}{dy}$, every equation of the form $\frac{d^2x}{dy^2} = Q$, and in which dy is constant, may be treated in the same way as that in art. 183, by making $\frac{dx}{dy} = q$, and $\frac{d^2x}{dy^2} = \frac{dq}{dy}$. It may also be reduced immediately to the form $\frac{d^2y}{dx^2} = P$, by passing by the formula of art. 93, to the hypothesis of dx being constant, which will be effected by the substitution of $\frac{-dxd^2y}{dy^3}$ in place of $\frac{d^2x}{dy}$.

If the proposed equation had been taken on the supposition of $\sqrt{dx^2 + dy^2}$ being constant, and if it involved only dx, dy, d^2y, or dy, dx, dx^2, it might still be treated in the same manner as that of art. 183, after transforming it into one in which dx was constant.

187. When the equation contains $\frac{d^2y}{dx^2}$, $\frac{dy}{dx}$ and the variable x, it may, as before, be transformed into a differential equation of the first order, by substituting pdx for dy, and $dpdx$ for d^2y; then, if the primitive of that differential equation, and thence the value of p in terms of x, can be found, we may have the value of y from the formula $y = \int pdx$; or else, if we have the value of x in terms of p, then, because $\int pdx = px - \int xdp$, we shall have $y = px - \int xdp$.

Ex. Let the equation be

$$-\frac{(dx^2 + d^2y)^{\frac{3}{2}}}{dxd^2y} = X \text{ or } -\frac{(1+p^2)^{\frac{3}{2}}dx}{dp} = X,$$

where x denotes a given function of x; then

$$\frac{dx}{X} = \frac{-dp}{(1 + p^2)^{\frac{3}{2}}} \text{ and } \int \frac{dx}{X} + C = \frac{-p}{\sqrt{1 + p^2}}.$$

Let V represent $\int \frac{dx}{X} + C$, then $p = \frac{V}{\sqrt{1 - V^2}}$, and $y = \int pdx + C' = \int \frac{Vdx}{\sqrt{1 - V^2}} + C'$; y is now expressed by means of x only. This is the analytical solution of the geometrical problem to find the nature of a curve whose radius of curvature shall be a given function of x, the absciss.

If we suppose $X = \frac{a^2}{2x}$, then $\frac{-p}{\sqrt{1 + p^2}} = \int \frac{2xdx}{a^2} = \frac{x^2}{a} + C$,

$$p^2 = \frac{dy^2}{dx^2} = \frac{x^2 + c}{a^4 - (x^2 + c^2)^2} \text{ and } y = \int \frac{(x^2 + c)dx}{\sqrt{\{a^4 - (x^2 + c)^2\}}};$$

here c is put generally for an indeterminate constant. This is the equation of the elastic curve.

188. If the proposed differential equation is composed of $\frac{d^2y}{dx^2}$, $\frac{dy}{dx}$, and y, we may, as before, put $p = \frac{dy}{dx}$, from which we get $\frac{d^2y}{dx^2} = \frac{dp}{dx} = \frac{pdp}{dy}$; the equation will now involve dp, dy, p and y only. When the primitive equation can be found, and thence the value of p in terms of y, we may find x by the formula $x = \int \frac{dy}{p}$; but when y is expressed by p, we may then employ the formula $x = \frac{y}{p} + \int \frac{ydp}{p^2}$.

189. Differentials of the second order, which have this form,

$$\frac{d^2y}{dx^2} + P\frac{dy}{dx} + Qy = R,$$

in which P, Q, R are any functions of x, are called *linear*, also equations of the *first degree*, because y is only of one dimension. It will easily be understood that the difficulty of finding the primitive equation will be greater than in the like equation of the first order; and, indeed, except in particular cases, there is no known method of reducing the integration to the finding of the differential of a single variable; that is, to the quadrature of a curve. If $\mathrm{R} = 0$, in which case the equation is

$$\frac{d^2y}{dx^2} + \mathrm{P}\frac{dy}{dx} + \mathrm{Q}y = 0,$$

it may be reduced to a differential equation of the first degree, by a very simple transformation. Let e, as usual, denote the base of Napier's logarithms; assume $y = e^{\int udx}$, then, regarding x as constant, we have

$$dy = udxe^{\int udx},\ d^2y = e^{\int udx}\ (dudx + u^2dx^2):$$

the value of dy and d^2y being substituted in the equation, and the common factors rejected, it becomes

$$du + (u^2 + \mathrm{P}u + \mathrm{Q})\,dx = 0.$$

When P and Q are constants, which may be represented by A and B, the equation becomes

$$du + (u^2 + \mathrm{A}u + \mathrm{B})\,dx = 0;$$

in which the variables are separated, if we give it the form

$$\frac{du}{u^2 + \mathrm{A}u + \mathrm{B}} + dx = 0.$$

As it is merely necessary to satisfy this equation, we may make $u = m$, m being any constant; then $du = 0$, and $m^2 + \mathrm{A}m + \mathrm{B} = 0$. This last equation gives, in general, two values of m; if we represent them by a and b, we shall have two values of $\int udx$; viz. $ax + c$ and $bx + c'$, and hence we have two values of y, viz.

$$y = e^{ax+c},\quad y = ^{bx+c'};$$

or, putting C for e^c, and C′ for $e^{c'}$,

$$y = \mathrm{C}e^{ax},\quad y = \mathrm{C}'e^{bx}.$$

These, however, are only *particular* values of the function y, because each contains only a single arbitrary constant; but by adding them, we get

$$y = \mathrm{C}e^{ax} + \mathrm{C}'e^{bx}$$

as the complete primitive equation.

To prove this, by differentiating, we get

$$\frac{dy}{dx} = a\mathrm{C}e^{ax} + b\mathrm{C}'e^{bx},\quad \frac{d^2y}{dx^2} = a^2\,\mathrm{C}e^{ax} + b^2\,\mathrm{C}'e^{bx}.$$

From these and the above primitive equation, we have, after eliminating C and C′,

$$\frac{d^2y}{dx^2} + (a + b)\frac{dy}{dx} - aby = 0.$$

This will agree with the proposed equation, if we give a and b such values that $a + b = \mathrm{P}$, $ab = -\mathrm{Q}$.

If a and b come out impossible quantities, the exponents of a and b in the value of y will have the form

$$a = \alpha + \beta\sqrt{-1},\quad b = \alpha - \beta\sqrt{-1};$$

we have then

$$y = \mathrm{C}e^{\alpha x + \beta x\sqrt{-1}} + \mathrm{C}'e^{\alpha x - \beta x\sqrt{-1}}$$
$$= e^{\alpha x}\left(\mathrm{C}^{\beta x\sqrt{-1}} + \mathrm{C}'e^{-\beta x\sqrt{-1}}\right);$$

This result is rendered real by eliminating the imaginary quantities, by means of sines and cosines; thus we have (ALGEBRA, art. 269),

$$e^{\beta x\sqrt{-1}} = \cos\beta x + \sqrt{-1}\sin\beta x,$$
$$e^{-\beta x\sqrt{-1}} = \cos\beta x - \sqrt{-1}\sin\beta x,$$
$$y = e^{\alpha x}\{(\mathrm{C}+\mathrm{C}')\cos\beta x + (\mathrm{C}-\mathrm{C}')\sqrt{-1}\sin\beta x\};$$

and making $\mathrm{C}+\mathrm{C}' = c$, $(c - c')\sqrt{-1} = c'$,

$$y = e^{\alpha x}\,(c\cos\beta x + c'\sin\beta x);$$

or, making $c = p\sin q$, $c' = p\cos q$,

$$y = pe^{\alpha x}\sin(\beta x + x).$$

When the roots a and b are equal, the value of y being reduced to

$$\mathrm{C}e^{ax} + \mathrm{C}'e^{ax} = (\mathrm{C} + \mathrm{C}')e^{ax},$$

it becomes incomplete. In this case we may proceed, as in art. 58, by supposing that a and b differ by a very small quantity. Let us suppose that $b = a + k$, there thence results

$$y = \mathrm{C}e^{ax} + \mathrm{C}'e^{ax+kx} = e^{ax}\,(\mathrm{C} + \mathrm{C}'e^{kx}):$$

developing e^{kx} according to the powers of k, we have

$$y = e^{ax}(\mathrm{C} + \mathrm{C}' + \mathrm{C}'kx + \mathrm{C}'\frac{k^2x^2}{2} + \&\text{c.})$$

or, putting $\mathrm{C} + \mathrm{C}' = c$ and $c'k = c'$

$$y = e^{ax}(c + c'x + c'k\frac{x^2}{2} + \&\text{c.})$$

This last expression, which satisfies the proposed equation for all values of k, agrees with it likewise if $k = 0$, or $b = a$; and, in that case, it becomes

$$y = e^{ax}(c + c'x).$$

190. When P and Q are variable quantities, functions of x, then if v and v' are two values of y which each satisfy the equation

$$\frac{d^2y}{dx^2} + \mathrm{P}\frac{dy}{dx} + \mathrm{Q}dy = 0,$$

we may take

$$y = cv + c'v$$

for the complete primitive equation. For then $dy = cdv + cdv'$, $d^2y = cd^2v + cd^2v$, and the differential equation becomes

$$c\left(\frac{d^2v}{dx^2} + \mathrm{P}\frac{dv}{dx} + \mathrm{Q}v\right) + c',\left(\frac{d^2v}{dx^2} + \frac{dv'}{dx} + \mathrm{Q}v'\right) = 0.$$

Now, by hypothesis,

$$\frac{d^2v}{dx^2} + \mathrm{P}\frac{dv}{dx} + \mathrm{Q}v = 0;\ \frac{d^2v'}{dx^2} + \mathrm{P}\frac{dv'}{dx} + \mathrm{Q}dv' = 0.$$

Therefore the equation is identical, and so the value of y is truly determined.

As an example of the integration of a differential equation of the second degree, see the article ARCH (art. 57).

191. We shall now give an example of the integration of a differential equation of the first degree and the second order.

Let the equation be

$$d^2y + ax^nydx^2 = 0.$$

If we suppose

$$y = \mathrm{A}x^{\alpha} + \mathrm{B}x^{\alpha+\delta} + \mathrm{C}x^{\alpha+2\delta} + \&\text{c.}$$

and that the series of exponents is an increasing one, or that δ is positive, we may, when x is supposed very small, conceive y to reduce itself to its first term, since the others are too small to be compared with this first. On this supposition, we may confine ourselves to assuming

$$y = \mathrm{A}x^{\alpha};\ \text{then}\ d^2y = \alpha\,(\alpha - 1)\,\mathrm{A}x^{\alpha-2}\,dx^2,$$

and the proposed equation will become

$$\alpha(\alpha - 1)\,\mathrm{A}x^{\alpha-2} + a\mathrm{A}x^{\alpha+n} = 0.$$

It is not possible to determine α so as to make the two exponents $\alpha - 2$ and $\alpha + n$ equal, except in the particular case of $n = -2$; but the exponent of x being greater in the second term than the first, we may neglect one of these terms in comparison with the other; and the equation may then be verified in two ways (by approximation), viz. by making $\alpha = 0$, and $\alpha = 1$, since upon either hypothesis the term $\alpha(\alpha - 1)\,\mathrm{A}x^{\alpha - 2}$ (the greatest in the equation) vanishes: A, therefore, remains indeterminate, and we have two series, one beginning with A, and the other with Ax.

If we take successively

$$y = \mathrm{A} + \mathrm{B}x^{\delta} + cx^{2\delta} + \&c.$$

$$y = \mathrm{A}x^{1+\delta} + \mathrm{B}x^{1+2\delta} + cx^{1+2\delta} + \&c.$$

and substitute for y these values, and for d^2y its corresponding values, we shall then find, by properly arranging the terms, that δ must be $= 2$; and, in either case, determining the values of the co-efficients A, B, C, &c. we arrive at these two series,

$$\mathrm{A} - \frac{a\mathrm{A}x^{n+2}}{(n+1)(n+2)} + \frac{a^2\mathrm{A}x^{2n+4}}{(n+1)(n+2)(2n+3)(2n+4)}$$
$$- \frac{a^3\mathrm{A}x^{3n+6}}{(n+1)(n+2)(2n+3)(2n+4)(3n+5)(3n+6)} + \&c.$$

$$\mathrm{A}x - \frac{a\mathrm{A}x^{n+3}}{(n+2)(n+3)} + \frac{a^2\mathrm{A}x^{2n+5}}{(n+2)(n+3)(2n+4)(2n+5)}$$
$$- \frac{a^3\mathrm{A}^{3n+7}}{(n+2)(n+3)(2n+4)(2n+5)(3n+6)(3n+7)} + \&c.$$

These developments are only particular cases, since they contain each but one arbitrary constant A; but, on account of the particular form of the proposed example (189), we shall obtain a general expression for y, by writing in the latter of them A_1 for A, and taking their sum.

Having now given as full a view of the principles of the fluxional calculus as we conceive to be compatible with the nature of our work, we shall conclude with a few more examples of its application to geometry.

Problem 1.

To find the length of the enlarged meridian in *Mercator's*, or rather *Wright's* projection of the sphere.

In this projection, the meridians and parallels of latitude are straight lines, which intersect each other at right angles; and the projection of any small arc of a meridian (as one minute), reckoned from any parallel, is to the projection of a like arc of longitude in that parallel, as radius to the cosine of the latitude of the parallel, that is, in the same ratio as the arcs themselves in the sphere. Supposing the radius of the sphere to be unity, let v be any arc of latitude reckoned from the equator, z its projection on the chart, or the *enlarged meridian.* Let v' and z' be any small increments of v and z; then, by the principles of the projection, $\frac{z'}{v'} = \frac{rad}{\cos v}$; therefore, putting the ratio of the differentials for the limit of the ratio of the increments, $\frac{dz}{dv} = \frac{1}{\cos v}$, and $dz = \frac{dv}{\cos v}$. Therefore, taking the integral (art. 155), $z = \mathrm{l.}\,\{\tan(45° + \frac{1}{2}v)\}$. Here no correction is wanted, because when $v = 0$, then $z = \mathrm{l.}\,(\tan 45°) = \mathrm{l.}\,(1) = 0$, as it should be.

Henry Bond, in the year 1650, discovered, by chance, that the enlarged meridian might be expressed by the logarithmic tangents of half the complements of the latitudes, a rule easily found from the preceding solution; but the difficulty of proving this was then considered so great, that Mercator offered to wager a sum of money against any person that should undertake to prove it either true or false. James Gregory, however, proved it in his *Exercitationes Geometricæ*, published in 1668; also Barrow, in his Geometrical Lectures: their demonstrations, however, were intricate. Afterwards Dr Wallis and Dr Halley gave demonstrations which were sufficiently simple and elegant.

Inverse Method.

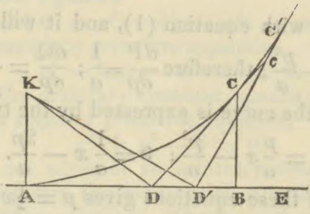
Problem 2.

If any number of straight lines are drawn according to some determinate law, it is required to find the nature of a curve to which these are tangents.

For example, let AE be a straight line given by position, and K a given point without it; let any number of lines KD, KD′, &c. be drawn to meet AE in D, D′, &c.; and let perpendiculars DC, D′C′, &c. be drawn to these lines; it is required to find the nature of the curve ACC′, to which these perpendiculars are tangents.

Without attending to the particular case, we shall resolve the general problem, and suppose AE to be the axis of the curve, A being the origin of the co-ordinates, and CD any position of the tangent, which meets the axis in D. From the point of contact C draw the perpendicular CB; and, considering C as a point in the curve, put AB $= x$, BC $= y$; but again considering C as any point whatever in the tangent, put AB $= x'$, BC $= y'$. Then, whatever be the conditions that determine the position of the tangent, the relation of x' and y', the co-ordinates of any point in it, may be expressed by the equation $y' = \mathrm{P}x' + \mathrm{Q}$, where P and Q are put to denote generally certain functions of constant quantities, and some quantity p, which has the same value for any given position of the tangent, but which changes its value if the tangent changes its position. For example, p may express the angle which the tangent makes with the axis, or it may represent the subtangent BD, &c.

Fig. 33.



Let us now suppose that the variable quantity p changes its value, and becomes $p + h$, and that C′ D′ is the new position of the tangent corresponding to $p + h$; then, considering P and Q as functions of p, by Taylor's theorem (art. 31),

$$\mathrm{P \ becomes \ P} + \frac{d\mathrm{P}}{dp}h + \frac{d^2\mathrm{P}}{dp^2}\frac{h^2}{2} + \&c.$$

$$\mathrm{Q \ becomes \ Q} + \frac{d\mathrm{Q}}{dp}h + \frac{d^2\mathrm{Q}}{dp^2}\frac{h^2}{2} + \&c.$$

The relation of x' to y' in the new position of the tangent will now be expressed by the equation

$$y' = \mathrm{P}x' + \mathrm{Q} + \left(\frac{d\mathrm{P}}{dp}x' + \frac{d\mathrm{Q}}{dp}\right)h + \mathrm{K}h^2 + \&c.$$

Where $\mathrm{K}h^2$ + &c. is put for all the remaining terms of the series.

Now, as this equation holds true of every point in the

Inverse Method.

tangent C′ D′, and the equation $y' = \mathrm{P}x' + \mathrm{Q}$ holds true of every point in the tangent CD, it follows that at c, the intersection of the two tangents, both equations must be true at the same time; therefore at c we have

$$\left(\frac{d\mathrm{P}}{dp}x' + \frac{d\mathrm{Q}}{dp}\right)h + \mathrm{K}h^2 + \&\text{c.} = 0;$$

and, dividing by h, $\frac{d\mathrm{P}}{dp}x' + \frac{d\mathrm{Q}}{dp} + \mathrm{K}h + \&\text{c.} = 0.$

Conceive now the two tangents to approach to coincidence; when C′ comes to C, then c will also fall at C; and h, and all the terms into which it enters, vanish; also x' and y' become x and y: and, to determine the nature of the curve, we have these two equations:

$$y = \mathrm{P}x + \mathrm{Q} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (1)$$

$$0 = \frac{d\mathrm{P}}{dp}x + \frac{d\mathrm{Q}}{dp} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (2)$$

By eliminating p from these, the resulting equation will express the nature of the curve.

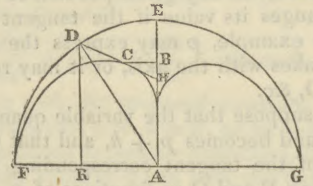
Ex. 1. Let us now recur to the particular case of AE, a straight line given by position, K a given point, and KDC a right angle: Draw KA perpendicular to AE; put $\mathrm{AB} = x$, $\mathrm{BC} = y$, $\mathrm{KA} = a$, and let AD be the variable quantity p. The triangles KAD, DBC are manifestly similar; therefore KA : AD = DB : BC, that is, $a : p = x - p : y$; hence $ay = px - p^2$, and $y = \frac{p}{a}x - \frac{p^2}{a}.$ Compare this with equation (1), and it will appear that $\mathrm{P} = \frac{p}{a}$, $\mathrm{Q} = -\frac{p^2}{a}$; therefore $\frac{d\mathrm{P}}{dp} = \frac{1}{a}$; $\frac{d\mathrm{Q}}{dp} = -\frac{2p}{a}$; hence the nature of the curve is expressed by the two equations

$$y = \frac{p}{a}x - \frac{p^2}{a};\ \ 0 = \frac{1}{a}x - \frac{2p}{a}.$$

The second of these equations gives $p = \frac{1}{2}x$; and hence the first becomes $y = \frac{x^2}{2a} - \frac{x^2}{4a}$; therefore $4\,ay = x^2$ is the equation of the curve, which is evidently a parabola, of which AK is the axis, K the focus, and A the vertex.

Ex. 2. Suppose a ray of light RD, coming from the sun, to fall upon FEG, the concave surface of a sphere, at D, and to be thence reflected in the direction DH; it is proposed to find the nature of the curve to which this, and all rays reflected in the same manner, are tangents.

Fig. 34.



Draw AD the radius of the sphere, and AE parallel to the incident ray RD; let C be the point in which the reflected ray touches the curve; let DC meet AE in H, and draw CB perpendicular to AE. Put $\mathrm{AD} = a$, $\mathrm{AB} = x$, $\mathrm{BC} = y$, and let p be the variable angle DAE.

By the principles of optics, AD bisects the angle RDH, which is equal to DHE, that is, to the sum of the angles DAH, ADH; therefore the angles ADH, DAH are equal, and angle $\mathrm{DHE} = 2p$. Now, by trigonometry,

$$\mathrm{AH} = \frac{\sin \mathrm{ADH}}{\sin \mathrm{AHD}} \times \mathrm{AD} = \frac{\sin p}{\sin 2p}\,a,$$

$$\mathrm{BH} = \frac{\cos \mathrm{CHB}}{\sin \mathrm{CHB}} \times \mathrm{CB} = \frac{\cos 2p}{\sin 2p}\,y;$$

$$\text{Hence } x = (\mathrm{AH} + \mathrm{BH}) = \frac{\sin p}{\sin 2p}\,a + \frac{\cos 2p}{\sin 2p}\,y,$$

$$\text{and } y = \frac{\sin 2p}{\cos 2p}\,x - \frac{\sin p}{\cos 2p}\,a \ldots\ldots\ldots\ldots\ldots\ldots (\alpha)$$

By comparing this with the general formula (1), it appears that

$$\mathrm{P} = \frac{\sin 2p}{\cos 2p},\ \mathrm{Q} = -\frac{\sin p}{\cos 2p}\,a;\ \text{hence,}$$

$$\frac{d\mathrm{P}}{dp} = \frac{2}{\cos^2 2p},\ \frac{d\mathrm{Q}}{dp} = -\frac{\cos p}{\cos 2p}\,a - \frac{2 \sin 2p \sin p}{\cos^2 2p}\,a.$$

Hence, by formula (2),

$$\frac{2x}{\cos^2 2p} = \left\{\frac{\cos p}{\cos 2p} + \frac{2 \sin 2p \sin p}{\cos^2 2p}\right\}a \ldots\ldots\ldots (\beta)$$

From equations (α) and (β) we readily find

$$x = (\tfrac{1}{2} \cos 2p \cos p + \sin 2p \sin p)\,a,$$

$$y = (\tfrac{1}{2} \sin 2p \cos p - \cos 2p \sin p)\,a;$$

and hence, by observing that $\sin 2p = 2 \sin p \cos p$, and that $\cos 2p = 2 \cos^2 p - 1 = 1 - 2 \sin^2 p$ (*Arithmetic of Sines*, ALGEBRA), we have also

$$x = \tfrac{1}{2} \cos p\,(1 + 2 \sin^2 p)\,a;\ \ y = \sin^3 pa.$$

From these equations it is easy to eliminate the trigonometrical quantities cos p and sin p, and the result will be the equation of the curve, which is an epicycloid. The curve in question is the *catacaustic* curve to a circle.

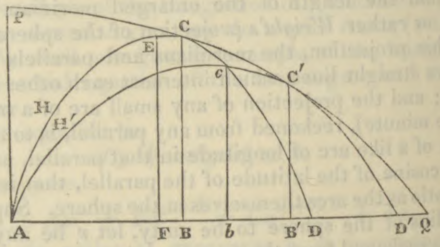
It is easy to see that the general problem, of which we have now given two examples, is very comprehensive. We may evidently find, by the formulæ (1) and (2), *catacaustic* and *diacaustic* curves in all cases whatever. These, and an infinite number of other geometrical problems, are contained in the following more general problem.

Problem 3.

Determine the nature of a curve which touches an infinite number of lines of a given kind, described upon a plane according to some determinate law. For example, suppose the lines to be parabolas described by a projectile thrown from an engine with a given velocity, at every possible elevation in a vertical plane.

Let HCD be any one of the lines of a given kind (a parabola, for example), and suppose it referred to an axis AB, by the rectangular co-ordinates $\mathrm{AB} = x'$ and $\mathrm{BC} = y'$. Let p denote some quantity belonging to the line or curve HCD, which has always the same value in the same curve, but which has different values in different curves. Thus, if the curve be a circle, p may be its radius; or if the curve be a parabola, p may be its parameter, &c. This quantity p may also by analogy be called the *parameter* of the curve HCD. Let us suppose the nature of this curve to be expressed by the equation

Fig. 35.



$$f(x', y', p) = 0 \ldots\ldots\ldots\ldots\ldots\ldots (1)$$

that is, let some function of x', y', and p, be supposed $= 0$. If p now be supposed to change its value, and become $p + h$, then the curve HCD will change its figure, and have some other position H′C′D′. Let $\mathrm{AB}' = x''$, and B′C′

$= y''$, be any co-ordinates of this other curve, and as, by hypothesis, the two curves are expressed by equations of the same form, we must have

$$f(x'', y'', p+h) = 0;$$

and this expression, by Taylor's theorem, is equivalent to

(2)

$$f(x'', y'', p) + \frac{d\{f(x'', y'', p)\}}{dp}h + \mathrm{K}h^2 + \&c.,$$

the differential being taken upon the hypothesis that p alone is variable, and $\mathrm{K}h^2 + \&c.$ being put for all terms of the series following the second, each of which is multiplied by a power of h.

Let the two curves intersect each other in c, and let $\mathrm{A}b = x$, and $cb = y$, be the common co-ordinates; then, as equation (1) holds true of every point in the curve HCD, and equation (2) holds true of every point in H′C′D′, both must hold true at once, if we substitute in them x and y, the co-ordinates belonging to their common point c; that is, we must have

$$f(x, y, p) = 0,$$

$$f(x, y, p) + \frac{d\{f(x, y, p)\}}{dp}h + \mathrm{K}h^2 + \&c. = 0;$$

and hence we must also have

$$\frac{d\{f(x, y, p)\}}{dp} + \mathrm{K}h + \&c. = 0.$$

Let C and C′ be now supposed the points in which the curves HcD, H′cD′ touch the curve PCC′Q, whose nature is required; then, if we suppose h to decrease continually, and at last to vanish, the points C′ and c will approach to C, and at last will coincide with it, so that x and y, which are co-ordinates of c, the intersection of the two curves HcD, H′cD′, will then become the co-ordinates of the curve PCQ. As all the terms which contain h will then vanish, we have evidently this rule.

Let the equation of the given curves be

$$f(x, y, p) = 0 \ldots\ldots\ldots\ldots\ldots\ldots(\alpha)$$

x and y being the co-ordinates, and p a variable parameter. From this equation, by taking the differential, supposing p to be variable, and all the other quantities constant, we deduce this other equation,

$$\frac{d\{f(x, y, p)\}}{dp} = 0 \ldots\ldots\ldots(\beta)$$

By these eliminate p, and the result will be an equation, which expresses the nature of the curve that touches all the given curves.

Ex. Let ACD, AC′D′, &c. be parabolas described by a projectile thrown from a given point A, with a given velocity, in a given vertical plane. It is proposed to find the curve PCQ which touches them all. Let EF be the axis of any one of the curves, AD an ordinate to the axis, $\mathrm{AP} = a$ the height due to the velocity of projection, $\mathrm{AB} = x$, $\mathrm{BC} = y$, the co-ordinates of C, any point in the curve. Put the parameter of the axis $= p$, and considering AD as a function of p, which is to be regarded as variable, put $\mathrm{AD} = q$.

By the theory of projectiles, $\mathrm{EF} = a - \frac{1}{4}p$, and by the nature of the parabola, $\mathrm{AF}^2 = p \times \mathrm{EF}$, and $\mathrm{AB} \times \mathrm{BD} = p \times \mathrm{BC}$; hence we have these two equations,

$$qx - x^2 = py, \ (1) \qquad q^2 = 4ap - p^2, \ (2)$$

From the first of these,

$$f(x, y, p) = x^2 + py - qx = 0:$$

and, taking the differentials, considering x and y as constant, and q as a function of the variable quantity p,

$$\frac{d\{f(x, y, p)\}}{dp} = y - \frac{dq}{dp}x = 0,$$

therefore $\frac{y}{x} = \frac{dq}{dp}$; but from equation (2), taking the differentials, $qdq = 2adp - pdp$, and hence $\frac{dq}{dp} = \frac{2a-p}{q}$, and by the first equation $\frac{y}{x} = \frac{q-x}{p}$, therefore $\frac{q-x}{p} = \frac{2a-p}{q}$, and hence $q^2 - qx = 2ap - p^2$; and substituting for q^2 its value given by equation (2), we get $qx = 2ap$; hence, and by equation (1),

$$p = \frac{x^2}{2a - y}, \qquad q = \frac{2ax}{2a - y}.$$

These values of p and q being substituted in the second equation, and the common denominator rejected, it becomes

$$4a^2x^2 = (8a^2 - 4ay - x^2)x^2.$$

Hence $4ay = 4a^2 - x^2$, and this is the equation of the curve PCQ, which is evidently a parabola having its focus at A, the common intersection of all the parabolas, its axis perpendicular to the horizon, and its parameter $= 4a$.

The geometrical theory comprehended in the second and third problems has a corresponding analytical theory relating to the integrals of certain differential equations. This is the theory of *singular* primitive equations, which are not included in the *complete* primitive equation. Thus, the differential equation

$$dy\sqrt{(x^2 + y^2 - b)} - ydx - xdx = 0,$$

has for its complete primitive equation

$$x^2 - 2ay - a^2 - b = 0,$$

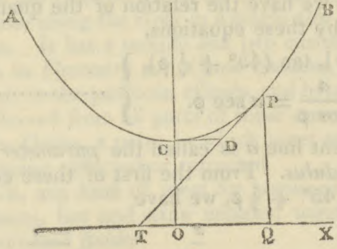
where a is the arbitrary constant quantity; but, besides this, it has a *singular* primitive equation,

$$x^2 + y^2 - b = 0,$$

which does not admit of an arbitrary constant, although it equally satisfies the differential equation, as is easily proved by differentiating. The bounds within which it was proper to confine this treatise have not allowed us to enter into this branch of the subject, which, although interesting, is yet not elementary.

Investigation of the Properties of the Catenary.

Suppose a chain or thread of uniform thickness, and perfectly flexible, but inextensible, to be fastened by its extremities at two points A, B in a vertical plane; by the action of gravity it will take the form of a curve ACPB, called the *catenary*.



The curve will evidently be all in one plane, and a horizontal line CD, in that plane, at C its lowest point, will manifestly touch the curve, which is retained at rest by a mutual balancing of the forces produced by the weight of the particles of the chain.

If we suppose its lowest point to be fixed at C, it is easy to understand that the part BC will not on that account change in the least its figure, because the tension of the chain at C, when it was free, is now replaced by the reaction of the force exerted in the horizontal direction CD.

Inverse Method.

The forces exerted on the points B, C will evidently be the same in quantity and in direction, whether the chain be considered as flexible, or rigid like a solid wire; hence it may be regarded as kept at rest by three forces, viz. its gravity acting vertically, and the re-actions of the tensions at B and C; the former exerted in the direction of a tangent to the curve at B, and the latter in the direction CD, the tangent at the lowest point C.

In like manner any portion PC between P and its lowest point may be considered as kept at rest by the joint action of the gravity of the mass PC, the tension of the chain at C, which is constant, and the tension at P, which is variable; and by the nature of an equilibrium (MECHANICS), these forces will be to each other as the sides of any triangle which are parallel to their directions. Draw a horizontal line OX in the plane of the curve as an axis, meeting the vertical through C in O, which may be taken as an origin of co-ordinates; draw PQ perpendicular to OX, and PT touching the curve and meeting the axis in T. From what has been explained, the tension of the curve at C will be to the weight of the matter in PC as TQ to PQ, that is, as radius to the tangent of the angle which PT makes with any horizontal line.

Put $OQ = x$, $PQ = y$, arc $CP = z$, angle $PTQ = \varphi$; and let a be the tension of the curve at the vertex C: we have then $a : z = 1 : \tan \varphi$; hence

$$\tan \varphi = \frac{z}{a} \ldots\ldots\ldots\ldots\ldots\ldots(1)$$

This is the distinguishing property of the curve, from which we are to deduce its other properties.

From equation (1), by differentiation,

$$\frac{d\varphi}{\cos^2 \varphi} = \frac{dz}{a}.$$

Now in all curves,

$$dz = \frac{dx}{\cos \varphi} = \frac{dy}{\sin \varphi};$$

hence we obtain

$$dx = a \,.\, \frac{d\varphi}{\cos \varphi}, \quad dy = a \,.\, \frac{d\varphi \sin \varphi}{\cos \varphi}.$$

From these, by integration,

$$x = a \, \text{l.} \tan (45° + \tfrac{1}{2} \varphi) + \text{const. (art. 155)}$$

$$y = \frac{a}{\cos \varphi} + \text{const.}$$

If we assume that OC measures the tension at C, which is a constant quantity, then because when $\varphi = 0$, $x = 0$, and $y = a$, we have the relation of the quantities x, y, φ, expressed by these equations,

$$\left.\begin{array}{l} x = a \, \text{l.} \tan (45° + \tfrac{1}{2} \varphi), \\ y = \dfrac{a}{\cos \varphi} = a \sec \varphi. \end{array}\right\} \ldots\ldots\ldots\ldots\ldots\ldots(2)$$

The constant line a is called the *parameter* of the curve, also its *modulus*. From the first of these equations, putting ψ for $45° + \frac{1}{2} \varphi$, we have

$$\tan \psi = e^{\frac{x}{a}}, \quad \cot \psi = e^{\frac{-x}{a}},$$

$$\tan \psi + \cot \psi = e^{\frac{x}{a}} + e^{\frac{-x}{a}}.$$

Now, $\tan \psi + \cot \psi = \dfrac{\sin \psi}{\cos \psi} + \dfrac{\cos \psi}{\sin \psi}$,

$$= \frac{2}{\sin 2 \psi} = \frac{2}{\cos \varphi} = \frac{2y}{a};$$

$$\text{therefore } y = \frac{a}{2} \left\{ e^{\frac{x}{a}} + e^{\frac{-x}{a}} \right\} \ldots\ldots\ldots\ldots\ldots\ldots(3)$$

This exponential equation expresses the relation between x and y by means of e, the base of Napier's logarithms. From this last equation, observing that $y = a \sec \varphi$, we get

$$\sec^2 \varphi = \tfrac{1}{4} \left\{ e^{\frac{2x}{a}} + e^{\frac{-2x}{a}} + 2 \right\},$$

$$\sec^2 \varphi - 1 = \tfrac{1}{4} \left\{ e^{\frac{2x}{a}} + e^{\frac{-2x}{a}} - 2 \right\},$$

$$\tan \varphi = \sqrt{\sec^2 \varphi - 1} = \tfrac{1}{2} \left\{ e^{\frac{x}{a}} - e^{\frac{-x}{a}} \right\}.$$

But it was found that $z = a \tan \varphi$,

$$\text{therefore } z = \frac{a}{2} \left\{ e^{\frac{x}{a}} - e^{\frac{-x}{a}} \right\} \ldots\ldots\ldots\ldots\ldots\ldots(4)$$

From formulæ (3) and (4) we have

$$y + z = ae^{\frac{x}{a}}, \quad y - z = ae^{\frac{-x}{a}} \ldots\ldots\ldots(5)$$

$$\text{therefore } y^2 - z^2 = a^2 \ldots\ldots\ldots\ldots\ldots\ldots(6)$$

hence again,

$$y = \sqrt{a^2 + z^2}, \; z = \sqrt{y^2 - a^2} \ldots\ldots\ldots\ldots\ldots\ldots(7)$$

and since from formula (5)

$$\frac{x}{a} = \text{l.} \frac{y + z}{a} = \text{l.} \frac{a}{y - z} \ldots\ldots\ldots\ldots\ldots\ldots(8)$$

$$\text{therefore also, } \frac{x}{a} \left\{ \begin{array}{l} = \text{l.} \dfrac{y + \sqrt{y^2 - a^2}}{a} \\ = \text{l.} \dfrac{z + \sqrt{z^2 + a^2}}{a} \end{array} \right\} \ldots\ldots\ldots(9)$$

Let s denote the area bounded by the arc PC and the straight lines CO, OQ, PQ; then, since $dx = \dfrac{a d\varphi}{\cos \varphi}$, and $y = \dfrac{a}{\cos \varphi}$, therefore

$$ds = y dx = \frac{a^2 d\varphi}{\cos^2 \varphi} = a dz.$$

$$\text{and } s = az \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(10)$$

Thus it appears that the arc CP is always proportional to the conterminous area CPQA. It is evident that the catenary, if inverted, would form an equilibrated arch. From this property it appears that if a wall, whose height above the crown of the arch is equal to the line CO, be horizontal at the top, the structure thus formed will constitute an equilibrated arch with a straight roadway. (See on this subject our article ARCH.) (R.)

FLY, a term usually applied to two-winged insects. See *Diptera*, in ENTOMOLOGY, *Index*.

FLY, in *Mechanics*, a cross with leaden weights at its ends; or rather, a heavy wheel at right angles to the axis of a windlass, jack, or the like, by means of which the force of the power, whatever it be, is not only preserved, but equally distributed in all parts of the revolution of the machine. See MECHANICS.

FLY ISLAND, an island in the South Pacific Ocean, discovered by De Maire and Schouten in 1616, and so named from the number of flies which were seen in it. Long. 150. 20. W. Lat. 15. S.

FLY TREE, in *Natural History*, a name given by the common people of America to a tree, the leaves of which, at a certain time of the year, are said to produce *flies*. On examining these leaves about the middle of summer there are found on them a sort of bags of a tough matter, of about the size of a filbert, and of a dusky greenish colour. On opening one of these bags with a knife, there is usually found a single full-grown fly, of the gnat kind, and a number of small worms, which in a day or two more have wings, and fly away in the form of their parent. The tree is of the mulberry kind, and its leaves are for the most part largely stocked with these insect bags; but they are generally found to contain the insects in their worm state; and when these become winged, they soon make their way out. The bags begin to appear when the leaves are young, and afterwards grow with them; but they never rumple the leaf or injure its shape. They are of the kind of leaf-galls, and partake in all respects, except size, of a species which is frequent on the large maple, or, as it is called, the *sycamore*.

FLYERS, the performers in a celebrated exhibition amongst the Mexicans, made on certain great festivals, which are described by Clavigero in his history of that people.

FLYING, the progressive motion of a bird, or other winged animal, through the air.

The parts of birds chiefly concerned in flying are the wings and tail; by the former the bird sustains and wafts itself along, and by the latter it is assisted in ascending and descending, keeping its body poised and upright, and obviating vacillations. It is by the size and strength of the pectoral muscles that birds are so well disposed for quick, strong, and continued flying. These muscles, which in men are scarcely a seventieth part of the muscles of the body, in birds exceed and outweigh all the other muscles taken together; so that if it were possible for a man to fly, his wings must be so contrived and adapted that he may make use of his legs, and not his arms, in managing them.

The tail is supposed by Willoughby, Ray, and others, to be principally employed in steering and turning the body in the air, like a rudder; but Borelli has put it beyond all doubt that this is the least use of the tail, which is chiefly intended to assist the bird in its ascent and descent in the air, and to obviate the vacillations of the body and wings; for as to turning to this or that side, that is performed by the wings and inclination of the body, with but very little help from the tail. The flying of a bird is in fact quite a different thing from the rowing of a vessel. Birds do not vibrate their wings towards the tail, as oars are struck towards the stern, but waft them downwards; nor does the tail of the bird cut the air at right angles as the rudder does the water, but is disposed horizontally, and preserves the same situation whichever way the bird turns. In fact, as a vessel is turned on a centre of gravity to the right, by a brisk application of the oars to the left, so a bird, in beating the air with its right wing alone towards the tail, will turn its fore part to the left. Thus pigeons changing their course to the left, would labour it with their right wing, keeping the other almost at rest. Birds of a long neck alter their course by the inclination of their head and neck; which altering the course of gravity, enables the bird to proceed in a new direction.

Artificial FLYING, that which is attempted by men, by means of mechanical contrivances.

The art of flying has been attempted by various persons in all ages. The superstitious Leucadians are reported to have had a custom of precipitating a man from a high cliff into the sea, first fixing feathers, variously expanded, round his body, in order to break his fall.

Friar Bacon not only affirms that the art of flying is possible, but assures us that he himself knew how to make a machine in which a man sitting might be able to convey himself through the air like a bird; and he further adds, that there was then a person who had tried it with success. The secret consisted in a couple of large thin hollow copper globes, exhausted of air; which being much lighter than common air, would sustain a chair on which a person might sit and be buoyed along. Father Francisco Lana, in his *Prodromo*, proposes the same thing. He computes, that a round vessel of plate brass, fourteen feet in diameter, weighing three ounces the square foot, will only weigh 1848 ounces, whereas a quantity of air of the same bulk will weigh $2155\frac{2}{3}$ ounces; so that the globe will not only be sustained in the air, but will carry with it a weight of $373\frac{2}{3}$ ounces; and by increasing the bulk of the globe without increasing the thickness of the metal, he conceives that a vessel might be made to carry a much greater weight. But the fallacy is obvious. A globe of the dimensions he describes, as shown by Dr Hook, would not sustain the pressure of the air, but be crushed inwards. Besides, in whatever ratio the bulk of the globe were increased, in the same ratio must the thickness of the metal, and consequently the weight, be increased; so that there would be no advantage in such augmentation.

The philosophers of the reign of Charles II. were mightily busied about this art. The celebrated Bishop Wilkins was so confident of success in the attempt, that he says he does not question but in future ages it will be as usual to hear a man call for his wings when he is going a journey, as it is now to call for his boots.

FLYING Fish, a name given to several species of fishes, which, by means of long fins, can keep themselves out of the water for some time. See ICHTHYOLOGY.

FOAL, or *COLT and FILLY*, the young of the horse kind. The word *colt*, among dealers, is understood of the male, and *filly* of the female.

FOCHAN, a town of China, near Canton, situated on the banks of the river on which the city stands, and extending three miles along the river in a single row of large well-built houses. It has a temple and two custom-houses.

FOCUS, in *Geometry* and *Conic Sections*, is applied to certain points in the parabola, ellipsis, and hyperbola, where the rays reflected from all parts of these curves meet.

FOCUS, in *Optics*, a point in which meet any number of rays, after being reflected or refracted.

FODDER, any kind of meat for horses or other cattle. In some places, hay and straw mingled together is peculiarly denominated *fodder*.

FŒNUS NAUTICUM. Where money was lent to a merchant to be employed in a beneficial trade, on condition of being repaid with extraordinary interest, in case such voyage was safely performed, the agreement was sometimes called *fœnus nauticum*, sometimes *usura maritima*.

FŒTOR, in *Medicine*, fœtid effluvia arising from the body, or any part thereof.

FŒTUS, the young of all viviparous animals whilst in the womb, and of oviparous animals before being hatched. The name is transferred by botanists to the embryons of vegetables. See ANATOMY.

FOG, or MIST, signifies the gross vapours floating near the surface of the earth. See METEOROLOGY.

FOGARAS, a market-town situated on the river Alt, in Hungary, the chief place of a district of the same name, in the division of the Seven Mountains. It contains a Catholic, a Lutheran, a Reformed, and two Greek churches, and 3200 inhabitants. Long. 24. 55. 9. E. Lat. 45. 48. 47. N.

FOGGIA, a city of the kingdom of Naples, the capital of the province Capilanata. It stands on an extensive plain, where several roads from the interior meet. It is extensive, has broad streets, and is surrounded with walls. It has several large fairs and markets, upon which the prosperity of the city chiefly depends. There are here several large magazines for storing corn, which is one of the chief branches of its trade. It is remarkable for the growth and preservation of capers, and produces abundance of wine and oil. It contains 20,680 inhabitants. Long. 15. 38. E. Lat. 41. 25. N.

FOHR, or FORA, an island belonging to the kingdom of Denmark, in the German Ocean, near the mouth of the river Illwe. It extends in north latitude from 54. 41. to 54. 46. and in east longitude from 8. 19. to 8. 31. It contains one market-town, called Westerlandfohr, and sixteen villages, forming sixteen parishes, and inhabited by 5670 persons, many of them sailors. A great number of the men are occupied in taking birds for the down and feathers, whilst the females make a large quantity of warm hosiery and gloves. They are said to have been originally a colony of Frisians, and still speak the language of that people.

FOIBLE, a French term, frequently used in our own language. It literally signifies *weak*, and in that sense is applied to the body and its parts, as *foible* reins, *foible* sight, and the like. It is derived from the Italian *fievole*, which again is the Latin *flebilis*, to be lamented or pitied. But it is chiefly used with us substantively, to denote a defect or flaw in a person or thing.

FOIL, in fencing, denotes a blunt sword, having a button at the end covered with leather, which is used in learning the art of fencing. See FENCING.

FOIL, amongst glass-grinders, a sheet of tin, with quicksilver, or the like, laid on the back of a looking-glass, to make it reflect.

FOIL, amongst jewellers, a thin leaf of metal placed under a precious stone, to make it look transparent, and give it an agreeable colour, either deep or pale.

FOIX, an arrondissement in the department of Arriège, in France, extending over 803 square miles. It is divided into eight cantons and 104 communes, inhabited by 78,280 individuals. The chief place, which gives name to the circle, is situated in a wide and fruitful valley, on the left bank of the Arriège. It is old and ill built, has some trade in hats, stockings, and caps, and contains 3600 inhabitants. Long. 1. 30. E. Lat. 43. 2. N.

FOKIEN, a large province of China. On the north it is bounded by the province of Tche-kiang, on the east by the Chinese Sea, on the south by Quang-tong, and on the west by Kiang-si. It comprehends under its jurisdiction the Pang-hon or Piscadore Islands, and also the island of Formosa. It has a fertile soil, and an agreeable, warm, and salubrious air; the mountains produce abundance of trees fit for ship-building; and agriculture is prosecuted with great skill on the plains, which yield rice in abundance. The high grounds are disposed in terraces, rising above one another, and water is conducted to them in pipes made of bamboo, which grows here in great plenty. The mountainous parts produce quicksilver, copper, lead, and iron; and it is even conjectured that there are gold mines, though these are not allowed to be worked. Manufactures are carried on in this province to a considerable extent. Steel implements are made, and also cloth from hemp and cotton, besides paper and pencils. The silks and cloth are of extraordinary fineness and beauty. The port of Enfouy in this province was formerly open to European vessels. The chief towns are Fou-tchoo, the capital, celebrated both for commerce and literature; Tsuen-tchosu, Yeu-ping, and Tchang-tcheou. The population is computed, though on very uncertain data, at 15,000,000.

FOKSCHANI, a city of Wallachia, in the circle Slam Rimnick, situated on the river Milkow. It contains fourteen churches and a monastery, with 4000 inhabitants, who trade in corn and cattle largely, and produce some good wine. Long. 26. 57. 25. E. Lat. 45. 38. 50. N.

FOLARD, JEAN-CHARLES DE, a distinguished French officer and military writer, descended of a noble but not affluent family, was born at Avignon on the 13th of February 1669. Even in his infancy he evinced a strong predilection for the profession of arms; and this inclination was confirmed by the perusal of Cæsar's *Commentaries*, which he received as a prize at the age of fifteen. In fact, he had scarcely attained his sixteenth year, when, making his escape from the paternal roof, he enlisted in a company of infantry which happened to be passing through Avignon; and although his father obtained his discharge, and shut him up in a convent, he again made his escape about two years thereafter, and shouldered a musket as a common soldier in the regiment of Berri. But his good conduct, as well as his birth, having soon brought him into notice, he obtained a sub-lieutenancy; and it was in this grade, the lowest of commissioned officers, that he saw service for the first time in the year 1688. Fortunately for his own improvement, however, he was employed in a corps of partisans, which, as all military men know, is the best school of instruction in great operations. Folard had thus occasion to observe, and to study with advantage, the most important branches of the military art. He examined all the communications, calculated the means of attack and defence, reconnoitred positions, constructed plans and maps, and thus, in short, prepared the materials of his voluminous works. It was during this period that he composed a little treatise entitled *De la Guerre de Partisan*, which has never been printed, but which Marshal de Belleisle long possessed in manuscript. The Marquis de Guébriant, colonel of the regiment of Berri, having taken a great interest in Folard, obtained for him a lieutenancy in his regiment; and immediately afterwards this corps received orders to proceed to Naples. It was during the long march which ensued that Folard, observing that the enemy received provisions and ammunition by sea, conceived the idea of surprising the post of Mesola, which protected the landing of the convoys. He accordingly submitted his plan to M. de Guébriant, by whom it was forwarded to the court, and there approved of; but another officer was charged with its execution, and the author remained unknown. The Duke of Vendôme, being informed of this injustice, appointed Folard his aid-de-camp, and at the same time procured for him the rank of captain. After giving him many proofs of confidence and esteem, this prince reluctantly consented to give up Folard to his brother, the Grand Prior, who then commanded in Lombardy. To the latter, Folard, ever zealous and active, rendered important services; but his talents, and above all his frankness, made him many enemies at head-quarters. He was at the taking of the posts of Rovero and Ostiglia, and also at the defence of the Casino della Bulino, where he distinguished himself greatly by his talents and his valour. It was by his advice that the Grand Prior caused this important post to be occupied; and Folard had, by the orders of his commander, repaired thither to make the necessary dispositions, when a numerous corps of the army of Prince Eugène appeared before it, with instructions to carry it at all hazards. The defensive preparations were still incomplete, and the garrison far from numerous; but, encouraged by Folard, they withstood the reiterated and furious attacks of the imperialists. The latter penetrated several times into the interior of the Casino; but by the intrepidity of the French, directed by Folard, they were each time repulsed, and ultimately compelled to discontinue their attacks. This brilliant affair, which procured him the cross of St Louis, is described by Folard in the notes to the third volume of his Polybius; and his relation has been cited by all military writers, not only as a model in itself, but also as containing one of the best lessons anywhere to be found on the defence of field-posts. Having rejoined the Duke of Vendôme, Folard rendered himself not less useful to that commander than he had previously done to the Grand Prior, and by his presence of mind, and the judicious advice which he gave at the battle of Cassano, fought on the 15th of August 1705, where he received two severe wounds, he acquitted himself as a brave soldier and skilful officer. This battle, remarkable for great efforts on both sides, for movements of all kinds, and for uncertain results, appears to have made a strong impression upon the imagination of Folard; and it is even said that amidst the suffering caused by his wounds he conceived his system of columns and deep formations. Soon after the battle of Cassano, Vendôme was ordered to proceed to Flanders, whither Folard, who was much attached to the duke, wished to accompany him; but he was retained with the army of Italy by the express desire of the Duke of Orleans, who had just assumed the command. The confidence which this prince reposed in him, and the freedom with which Folard continued to express his opinions, careless whom they might offend, once more made him dangerous enemies amongst the staff. From a note to Polybius it appears, indeed, that it was entirely owing to their insinuations that he received orders to shut himself up in Modena. It had become evident that this city would be attacked; and as the command was then in the hands of a person named Bar, upon whom no reliance could be placed, and who, in fact, had resolved to surrender the place at the first summons, the chevalier, firmly resolved to do his duty, soon found himself involved in serious disputes with this cowardly superior in command. In his *Traité de la Défense des Places*, he has given a long recital of the indignities he experienced at the hands of this miscreant, who even attempted his life; but although Folard unveiled his proceedings without reserve, the traitor escaped with impunity. Soon after the capitulation of Modena, the chevalier, to his great joy, received orders to join the Duke of Vendôme, who had in fact reclaimed his former aid-de-camp; and having taken Versailles in his way, he was there presented to the king, who received him graciously, and granted him a pension of four hundred francs. Upon his arrival in Flanders, Folard induced the Duke of Burgundy, then in command of the army, to attack the isle of Cadsand. The enterprise succeeded beyond all calculation, and its author was appointed commandant of the fort of Lettingen. But the young prince, who had at first appreciated the advice of the chevalier, afterwards paid as little regard to his opinions as to those of Vendôme; and, in spite of their joint remonstrances, he persisted in remaining inactive in presence of the allies, whilst Prince Eugène was engaged in taking Lille. The counsels which Folard gave to Marshal Villars for the relief of Mons were also disregarded. But his services were nevertheless recognised and appreciated at court; and it was about this time that the minister conferred on him a second pension of six hundred francs; a new favour, which was the more considerate, as he had been once more severely wounded at the battle of Malplaquet. Redoubling his zeal and activity, though no longer able to take part in the movements of the army, Folard followed them on the map and in his imagination, incessantly dreaming of plans and operations, and sending all his ideas to the generals. One day he caused himself be carried on a litter to the quarters of Marshal Boufflers, to give a piece of advice, which, however, was disregarded. Such zeal was no doubt indiscreet; and the manners of Folard were, it seems, calculated to injure the best observations. Thus M. de Montesquiou rejected the advice which the chevalier gave him respecting the position occupied by him at Douai; and it was only after his defeat that this general discovered his error in neglecting the counsels of the uncourtly chevalier. Some months afterwards Folard found Marshal Villars more docile; and he had the satisfaction of seeing the army put in motion, in consequence of a plan which he had transmitted to that general. Having subsequently been sent to M. de Guébriant, who occupied Aire, then threatened with a siege, he was taken prisoner on the road by the light troops of the enemy, who made vain attempts to discover the nature of his instructions. Prince Eugène, indeed, had recourse to every means of seduction in order to induce him to enter the service of the emperor; but Folard, immovable in his fidelity, resisted all these attempts, and even found an opportunity during his captivity of serving his sovereign, by misleading the prince as to the operations of the French army. As soon as he was exchanged, which the Duke of Burgundy lost no time in effecting, he obtained the command of the garrison of Burburg, the title and appointment of which he retained until his death.

The peace of 1712 having left him without active professional employment, Folard commenced his commentaries; but being still of an age not to remain long in a state of inaction, he profited by the alarms which the Ottomans occasioned to the knights of Malta in 1714, and, with the permission of the court, repaired to that island. The grand master received him with much cordiality; but Folard soon gave way to his characteristic vanity and indiscretion towards the French engineers, who, like himself, had come to offer the knights their best services for the defence of the island. Dissatisfied because his opinion had not prevailed, he refused the cross of the order, which was offered him, according to the ordinary usage in such cases, and immediately returned into France. But his warlike activity was not yet exhausted. The fame of the exploits of Charles XII. then resounded throughout all Europe, and Folard eagerly desired to witness the achievements of so celebrated a hero. Accordingly he embarked for Sweden on board a vessel, which was shipwrecked almost at the moment of landing; and having been saved in a sloop, he reached Stockholm destitute of every thing. The king, however, received him favourably, and listened to his discourses upon tactics with extreme complaisance. Nothing could possibly be more agreeable to Folard, who, delighted with his royal pupil, at once preferred Sweden to France as a place of residence for a soldier. Nevertheless he soon afterwards returned into his own country, for the purpose of promoting the plans of the Baron de Goërtz. But the project with which the baron was entrusted having been overthrown by his arrest, Folard returned to Stockholm, and accompanied the king of Sweden in his expedition to Norway. Immediately after the death of Charles before Frederickshall, he returned to France, and was promoted to the rank of colonel in the regiment of Picardy. In this capacity he served his last campaign in 1719, under the Duke of Berwick, in the short war which France had then to maintain in Spain. A general peace speedily ensued, and Folard then saw himself condemned to a state of repose, which as yet he had never known or enjoyed.

From this time he devoted himself entirely to his literary pursuits, and was ere long in a condition to present to the

Duke of Orleans, then regent, his book entitled *Nouvelles Découvertes sur la Guerre*, published at Paris in 1724. His next aim was to find a subject with which it might be possible for him to connect the results of his lengthened observations, and also to combine the explanation of his new system. And with this view he made choice of the history of Polybius. That work is, without any doubt, the most exact, and at the same time the most judicious, in a military point of view, of all the historical writings of antiquity; and hence Folard could not possibly have made a better choice. But not being acquainted with Greek, he was obliged to entrust the translation to Dom Thuillier, whilst he simultaneously laboured at his commentaries, which he placed in the form of notes at the end of each chapter of Polybius. These commentaries are of an unexampled prolixity, and the style frequently descends to triviality; in the same page things the most incoherent are often jumbled together; and he makes continual efforts to connect everything with his system of columns and deep formations. But however imperfect the work of Folard may be considered in a literary point of view, military men will find it in many respects eminently useful; for, besides judicious remarks and learned researches respecting the wars of the ancients, we meet with much valuable information, which we cannot help regretting that the historians of this period should not have oftener referred to. He explains the causes and the results of these events with a frankness which was often hurtful to himself, but which will always be useful to posterity. This frankness, indeed, which had raised up so many obstacles to his advancement whilst he had arms in his hands, also created opposition to his projects after he became author. When he had reached the sixth volume of his Polybius he was ordered to refrain from indulging in the same sort of discussions as in the preceding portion of the work. Of this injunction he complains bitterly in the preface to the volume in question, and says that he has been restrained precisely at the place where his author became more interesting, and where he felt himself inspired by events more worthy of remark and annotation.

Folard has prefixed to this immense work his *Treatise on Columns*, and the deep order, which he regards as the basis of all good tactics. His opinion in favour of deep formations encountered much opposition at the time when it was first promulgated, and the controversy which it then occasioned has not yet been altogether set to rest. The most judicious of his critics was General Savornin, a Swiss officer in the service of Holland, who published anonymously *Les Sentiments d'un Homme de Guerre sur le nouveau Système de Folard*. Of all his adversaries this author is the one whom he treats with the greatest respect in the prefaces to his volumes, which, as is well known, he converted into a sort of field of battle, where he attacked *à outrance* those who had ventured to dispute his opinions. But the best part of the commentaries on Polybius is undoubtedly that where Folard treats of the tactics of the ancients, and particularly of their manner of attacking and defending strong places. This is a subject which he had maturely considered, with reference to the instruments of war in use amongst the ancients. He had even caused to be constructed a catapult, the experiments made with which transported him with admiration; and he did not hesitate to affirm, that if it were possible for him, with the machines and means of the ancients, to attack a place defended by the artillery of the moderns, he would make sure of taking it in a very short time. Such an assertion, it may very easily be imagined, was much better calculated to astonish than convince. His ideas on strategics were scarcely, if at all, less extraordinary; and his system of columns and deep formations will be sufficiently appreciated if we consider that, in the numerous wars which have occurred since its publication, there is no sovereign nor general who has deigned to put it fully in practice. It must be admitted, however, that attacks in close columns, which have been so generally and so successfully employed in our time, are in some sort an imitation of Folard's system. This method no doubt proves that the deep order is sometimes the best; but attacks in close columns, by platoons, divisions, or battalions, such as have latterly been practised, present advantages which Folard had never dreamed of, namely, the power of deploying if necessary, of changing the front and direction of the mass with extreme facility, and of passing rapidly from the deep to the extended, and from the extended to the deep formation.[1] Folard, if we may be allowed the expression, was so deeply infected with his system and his discoveries, that he saw everywhere the deep order and columns of attack. He had read little of the Bible; but happening one day to take up that sacred book, he exclaimed, on reading the first page, "Do you know that Moses must have been a great captain. He has discovered my column."

---

[1] "In general the formations of a good military nation are extended, whilst those of a bad one are deep." So says Count von Bismark (*Tactics of Cavalry*, p. 200, Engl. transl.); and the remark is undoubtedly well founded. At the same time, the diminution of depth in the formation of modern armies has been a natural consequence of the constantly augmenting power of artillery and of small arms. In ancient times battles were generally decided by bodily strength; and as armies had then no concentric fire to apprehend, they could with safety assume that deep formation which was calculated to overwhelm the enemy by impulsion alone. But the invention of gunpowder, and the destructive effects of cannon fire, arising from the improvement of artillery, necessitated in modern times a departure from the dense formations of antiquity. This was strongly felt by Gustavus Adolphus, who, whilst his opponents, Tilly and Wallenstein, formed their infantry in solid masses, drew up his men six deep, and, in this extended formation, overwhelmed the columns of his adversaries. If we may judge from recent examples, however, deep formations are not even now so inappropriate as may be imagined; and, absurd as the columns of Folard may appear, it was by the employment of analogous masses, directed with a celerity which at once increased their momentum and diminished the ravages of cannon fire, that Napoleon proved so often successful. In the order of battle laid down by Jomini as combining in the greatest degree mobility with solidity, the corps destined for the attack are arranged in two lines of battalions, each battalion being formed in column of grand divisions. "La troupe d'attaque," says he, "aussi bien que la réserve, ne sauraient être mieux disposées qu'en colonnes d'attaque par la centre; car la réserve, devant être prête à tomber sur l'ennemi au moment décisif, doit la faire avec force et vivacité, c'est-à-dire, en colonnes." (*Traité des Grandes Opérations Militaires*, tom. iii. c. 35, p. 357.) The Duke of Wellington, it is true, generally attacked with deployed lines; but these, it is to be observed, were sometimes of deep formation. The body of English guards which so successfully attacked the columns of the imperial guard at the close of the battle of Waterloo was formed four deep; and the final charge *en muraille* executed by the British line on that day was also made in the same formation. It is to be observed, however, that the columns of the imperial guard were torn up and shattered by a close concentric fire of artillery, before the English guards advanced to the attack. To this indeed columnar formations are always more or less exposed; for though the evil may be lessened by celerity of movement, it cannot be avoided, and a rapid advance is always of itself productive of some confusion and disorder. Hence the attack in column has by no means been attended with the results which the Chevalier Folard expected from it. The Duke of Wellington always deployed before battle, and at Waterloo defeated an army drawn up in columns of attack, this being one of the few instances where his lines exceeded the usual formation of two deep. The French lost the battle of Essling by attacking the centre of the Austrian line in column. Massena's columns failed at Busaco; Victor's were baffled at Barossa; and even the Spaniards broke two columns of the French army at St Marcial. At Waterloo, again, the repeated advances of Napoleon's columns proved unavailing against the linear formation of the British; and although at the close of the day the chosen columns of the imperial guard advanced with a determined bravery which would have done honour to the troops of any nation, they had no better success. These facts naturally shake our faith in columns, and serve to confirm the remark of Bismark, that the formations of the best military nations are not deep, but extended. An undisciplined multitude suddenly drawn together, or an army possessing little moral force, may be appalled by the imposing appearance of

Count Saxe, who had known Folard in Sweden, appears to have attached much importance to his opinions. The esteem which that able commander entertained for him may be judged of from his letters, some of which are subjoined to the work entitled *Mémoires pour servir à l'Histoire de M. le Chevalier de Folard*, Paris, 1753. Folard was a good engineer, and excelled both in drawing and in the construction of military plans. It was from designs by him that the Abbé Gédoyn was enabled to give the plans of the different battles in his translation of Pausanias. Folard has been denominated the French Vegetius; but he himself would not have been much flattered by this title, as he often speaks with contempt of Vegetius. As he cites a great number of ancient authors, he has often rectified their text, which had been altered by the copyists; and he has also sometimes indicated mistakes in the translations of their works. The publication of his Polybius procured him a great reputation in Europe, and was soon followed by his admission into the Royal Society of London. The king of Prussia, Frederick the Great, having desired to make trial of his system, the chevalier was invited to repair to Berlin, to be a witness of the experiment; but his advanced age prevented him from undertaking so long a journey. Nevertheless this warlike monarch attached but little importance to the writings of Folard, which he has even treated as visionary and extravagant in several passages of his correspondence, and particularly in the volume which he caused to be printed in 1761, under the title of *L'Esprit du Chevalier de Folard*, in 8vo. In the preface to this compilation, Frederick says, "Il (Folard) avait enfoui des diamants, au milieu du fumier; nous les avons retirés. On a fait main basse sur le système des colonnes: on n'a conservé que les manœuvres de guerre, dont il donne une description juste; la critique sage qu'il emploie sur la conduite de quelques généraux Français, certaines règles de tactique, des exemples de defenses singulières et ingénieuses, et quelques projets qui fournissent matière à des réflexions plus utiles encores que ces projets mêmes." Such was the opinion of the greatest captain of his time respecting the writings of Folard. The literary labours of this tactician impaired his health more rapidly than the fatigues of war, which, indeed, appear to have made little or no impression on his constitution. Wishing once more to visit his native city, Folard repaired to Avignon in 1750, and died there on the 23d of March 1752, at the advanced age of eighty-three.

This able warrior failed to attain the first rank in the army, though he had eagerly aspired to it; nevertheless he was content with his lot; and with a small patrimony, and some pensions which had been granted him by the king, he found means to do good. His last years would have been perfectly happy if he had not recklessly disturbed their serenity by throwing himself *à corps perdu* into an imprudent controversy, where, from his great irascibility and excessive self-love, he often furnished arms against himself. Another circumstance also served to embitter his declining days. Having allowed himself to be drawn into the party of the Appellants, as they were called, he was represented by the pamphleteers of the time as one of those who had given themselves up to visionary convulsions upon the tomb of Deacon Pâris. The new sect was of course delighted to be able to refer to such evidence in support of its absurd pretensions; and it is easy to conceive the ridicule which this must have drawn down on the old chevalier. The Cardinal de Fleury was in fact so much displeased with him that he ordered Folard to quit Paris; and it was only at the earnest entreaty of several generals, who bore testimony to his numerous and important services, that this order was recalled. During his whole life Folard had enjoyed the most robust health. But a single infirmity afflicted him from his youth, and increased with his age; we mean, a natural deafness, which had often nearly proved fatal to him in the field of battle. In his old age he was almost entirely destitute of the sense of hearing.

Folard's military opinions, which had excited so much discussion during his lifetime, occasioned a great deal more long after his death. His system of columns, warmly attacked in the *Mémoires Militaires* of Colonel Guischardt in 1758, and also in the *Mémoires Critiques* of the same author in 1774, was defended with much heat in the *Recherches d'Antiquités Militaires* of the Chevalier de Lalooz, Paris, 1770, and likewise in another volume published by the same author in 1776, under the title of *Defense du Chevalier Folard*. The history of Polybius, with the commentaries, was first printed at Paris in six vols. 4to, 1727–1730, and next at Amsterdam, 1753, in seven vols. 4to. The seventh volume, which is a supplement, is not found in the Paris edition. It contains, 1. *Les Nouvelles Découvertes sur la Guerre;* 2. *Lettre Critique d'un Officier Hollandais* (Terson); 3. *Sentiments d'un Homme de Guerre* (Savornin) *sur le Système Militaire du Chevalier de Folard;* 4. Answer of Folard to his critics. The commentaries on Polybius have been abridged and printed separately by Chabot, Paris, 1757, in three vols. 4to. There are two German translations, one printed at Berlin, and the other at Vienna. The observations on the battle of Zama, and on the history of Epaminondas, which had been published separately in 1738 and 1739, form part of the commentaries on Polybius; and, as already stated, the author has also combined with these commentaries his *Traité de la Colonne*, as well as that on the attack and defence

---

a column advancing to the attack, and give way from apprehension; but no such effect can be produced where courage and discipline are found united. This was signally exemplified at Albuera, where, in the attack on the key of the position, the French columns, though momentarily successful, found it impossible to deploy, under the incessant and dreadful vollies, which swept away the head of every formation, and, after a desperate and unavailing struggle, were driven headlong down the ascent. Every order is good against troops who do not defend themselves; in that case it is only necessary to march. But against troops who do defend themselves, and who to natural courage unite that discipline which teaches them to preserve unshaken the stability of their order, the attack in column will seldom prevail, unless combined with extended formations. As much, however, may be said on both sides, many writers have been led to maintain extreme opinions on the subject, as the following passage, extracted from a very ingenious essay on tactics, will abundantly testify. "The victories gained by the natural gallantry and intelligence of the French soldiers, in spite of the system under which they were supposed to fight, gave military opinion a bias in favour of masses and solid formations, simply disgraceful to human understanding, at a time when hundreds of pieces of artillery already frowned destruction over every field of battle. Nothing but the most profound ignorance of every principle of professional science, as well as the most callous indifference to the lives and sufferings of men, could for a moment have tolerated a system that tended to eradicate from the heart every feeling of humanity, and to stifle military genius in the bud. It was well calculated for ignorant, grasping, and ambitious leaders; it enabled such men, in the absence of military talents, to gain battles by quenching with the blood of their own soldiers the fires of the enemy, and literally to overwhelm the foe with the mangled bodies of the human victims so lavishly placed at their disposal by ruthless ukases and conscriptions." (Mitchell's *Essay on Tactics*, part iv. United Service Journal, July, 1834.)

of strong places. Folard is likewise the author of a tract, entitled *Fonctions et Devoirs d'un Officier de Cavalerie*, Paris, 1733, in 12mo. (A.)

FOLCLANDS, or Folklands. Copyhold lands were so called in the time of the Saxons, as charter lands were called *boclands*. *Folkland* was *terra vulgi* or *terra popularis*, the land of the common people, who had no certain estate therein, but held it under the rents and services accustomed or agreed, at the will only of their lord the thane; and it was therefore not put in writing, but accounted *prædium rusticum et ignobile*.

FOLCMOTE, or Folkmote (Saxon, *Folcgemote*, that is, *conventus populi*), is composed of *folk*, *populus*, and *mote* or *gemote*, *convenire*, and originally signified a general assembly of the people called together to consider of and order matters of the commonwealth. According to Spelman, the *folcmote* was a sort of annual parliament or convention of the bishops, thanes, aldermen, and freemen, which assembled upon every May-day, and in which the laymen were sworn to defend one another and the king, and to preserve the laws of the kingdom, after which they consulted of the common safety. But, from the laws of the Saxon kings of England, Dr Brady infers that it was an inferior court, held before the king's *reeve* or steward every month, to do *folk* right, or compose smaller differences; and that from it there lay an appeal to the superior courts. (*Gloss.* p. 48.) Squire seems to think that the *folkmote* was not essentially distinct from the *shiremote*, or common general meeting of the county. (See his *Angl. Sax. Gov.* 155, n.) Manwood mentions *folcmote* as a court holden in London, in which all the *folk* and people of the city did complain of the mayor and aldermen for misgovernment within the said city; and this word is still in use, denoting *celebrem ex tota civitate conventum.* According to Kennet, the *folcmote* was a common council of all the inhabitants of a city, town, or borough, convened by sound of bell, or otherwise, to the *Mote Hall* or *House;* or it was applied to a larger congress of the freemen within a county, called the *shiremote*, where formerly all knights and military tenants did homage to the king, and elected the annual sheriff on the first of October, until 1315, when, to avoid tumults and riots, this popular form of election was, by 3 Edward I. merged in nomination by the king. After this time the city *folkmote* was swallowed up in a select committee or common council, and the county *folkmote* in the sheriff's tourn and assizes.

The word *folkmote* was also used to signify any kind of popular or public meetings, as those of the tenants at the *court leet* or *court baron*, in which signification it was of a less extent than that above explained. (*Paroch. Antiq.* 120.)

FOLENGO, Theophilus, better known by his assumed name of *Merlin Cocaio*, an eccentric genius, and burlesque poet, was descended of a noble family of Mantua, and born at a place called Cipada, beyond the suburb of St George on the lower lake, in the year 1491.[1] From his infancy he showed great quickness and vivacity of mind, a decided taste for poetry, and a singular facility of turning everything which occurred into verse. According to Tomasini and others, he completed his studies at Bologna, and at the age of sixteen entered the order of Benedictines of the congregation of Monte Cassino, near Brescia, where his elder brother had taken the vows about three months before. He then assumed the name of Theophilus instead of Jerome, which was his baptismal name, and eighteen months afterwards he made profession as Benedictine. At first his life was regular; but a new superior of the monastery of Brescia, where he had become professed, having permitted or introduced great disorders there, Folengo, led away by bad example, forgot his vows, and ended by quitting the monastery and his habit together, to stroll about with a pretty woman who had captivated his fancy. This young person, who is said to have been well born, is not directly mentioned by him in his works; but as he has put the letters of her name to a species of canzone or ode, consisting of thirteen verses, we thence collect that she was called Girolama Dieda. With this female he wandered about for ten years, having, as appears, no other resource for procuring a livelihood than his talents and his verses. He had commenced a poem in Latin, which, as far as it went, displayed much elegance; but he soon quitted serious poetry, in which he could at most only hope to obtain a secondary rank, for a kind which he called Macaronic, and in which he conceived himself qualified to occupy the first place. The basis of the language employed by him is Latin, mixed with Italian words, and still more with the Mantuan patois, which was his mother tongue, and to which he gave Latin terminations. In his poem he recounts the ridiculous adventures of a hero called Baldus, among which are several which had happened to himself; and under the mask of burlesque and buffoonery may be found thoughts and maxims instinct with good sense, not to mention original and piquant touches of satire on the conduct of the great, the vanity of titles, and the different pursuits of men. It has been alleged that he gave the name of Macaronic to this strange species of composition, in which Latin is intermixed with Italian and Mantuan, because macaroni is seasoned with a mixture of flour, butter, and cheese; and in fact, to a mind like his, this fanciful and grotesque resemblance was sufficient. Instead of dividing his poem into books or cantos, he accordingly divided it into macaronis (*macaronea prima*, *macaronea secunda*, etc.), of which there were seventeen in the first edition and twenty-five in the subsequent ones; and he published the whole under the name of *Merlinus Cocajus*, which afterwards became famous. In a few years several editions were published; but the success of these facetious productions did not prevent their being bitterly criticised. The author was severely censured, both for the style in which he wrote, and the license of ideas and expressions in which he indulged; a circumstance which irritated him so much that, changing his style, or rather language and name, he composed in three months a satirical Italian poem, in eight cantos, on the infancy of Roland, to which he gave the title of *Orlandino*, and affixed the name of *Limerno Pitocco;* *Limerno* being the anagram of *Merlino*, and *Pitocco* or mendicant being significative of the state to which he was occasionally reduced. He had nevertheless made many friends in the world by the reputation which he had acquired, the extent of his knowledge, and the agreeable qualities of his mind; and he had even retained some in the cloister, into which, when tired of a wandering and miserable life, he was received back with open arms. He signalized his return by a work on the subject of his conversion, entitled *Il Chaos del Triperuno*, or The Chaos of Three for One, meaning himself, who had been successively Theophilus Folengo, Merlin Cocaio, and Limerno

---

[1] Folengo, in his verses, has several times mentioned the place of his birth in his own peculiar vein:

> Magna suo veniat Merlino parva Cipada.—
> Mantua Virgilio gaudet, Verona Catullo,
> Dante suo florens urbs Tusca, Cipada Cocajo.—
> Nec Merlinus ego, laus, gloria, fama Cipadæ, etc.

Pitocco. The work is a medley of verses, songs, and narrations, in Latin, Italian, and the Macaronic dialect, in short, a veritable chaos, divided into three parts, called, after Statius, *Sylvæ*. He then applied himself to correct his other works, and the *Orlandino* appeared in seven cantos instead of eight, with corrections and considerable suppressions, especially in the seventh canto. He also undertook to chasten the Macaronics; and having completed this labour, he entrusted the publication of the purified edition to his brother Francisco Folengo. But although these two works were thus rendered less exceptionable and more orthodox, the corrected editions have fallen into oblivion. Folengo appears to have remained during several years at Capri, a country-house belonging to his order, between Brescia and Bergamo, and, in fact, to have divided his time between this retreat and Brescia till 1536 or 1537, in one or other of which years he composed his Italian poem on the Humanity of the Son of God, the most orthodox of all his works, and which would be the most edifying if one could really be edified by that which is unreadable. He was then sent into Sicily to the monastery of St Martin *delle Scale*, where he appears to have remained till 1543, when he returned into Italy, and retired to the convent of the Holy Cross of Campesa, near Bassano, on the banks of the Brenta, where he died in little more than a year afterwards, 9th December 1544, in the fifty-third year of his age. The following is a list of his works: 1. *Merlini Cocaji Poëtæ Mantuani Macaronices* libri xvii. Venice, 1517, in 8vo; 2. *Orlandino, per Limerno Pitocco da Mantova composto*, Venice, 1526, in 8vo; 3. *Chaos del Triperuno, con privilegio*, Venice, 1527, in 8vo; 4. *La Humanità del Figliuolo di Dio, in ottava rima, per Theophilo Folengo Mantovano*, Venice, 1533, in 8vo; 5. *Joannis Bapt. Chrysogoni Folengii Mantuani anchoretæ dialogi quos Pomiliones vocat*, 1533, in 8vo; 6. Several *Poems*, the greater part on subjects of devotion, and some also in the Macaronic vein, which have not been printed. (A.)

FOLIATING OF LOOKING-GLASSES, the spreading the plates over with quicksilver, after they have been polished, in order to reflect the image. The mode in which it is performed may be shortly described. A thin blotting paper is spread on the table, and sprinkled with fine chalk, and a fine lamina or leaf of tin, called *foil*, is laid over it; upon this is poured mercury, which is to be distributed equally over the leaf; a clean paper is then laid upon the mercury, and over that the glass plate, which is pressed down with the right hand, and the paper gently drawn out with the left. This being done, the plate is covered with a thicker paper, and loaded with a greater weight, that the superfluous mercury may be driven out, and the tin adhere more closely to the glass; and when it is dried, the weight is removed, and the looking-glass complete.

FOLIGNO, a city of the delegation Perugia, in the papal dominion, in Italy. It is situated in a rich and fertile plain, near the river Topino, whence it receives the waters of the Maroggia. It contains eight churches, twelve monasteries, eight nunneries, and a magnificent state-house, in which is a museum of antiquities. The inhabitants, amounting to 15,102, are employed in bleaching wax and making tapers, in woollen manufactures, in making paper, and various conserves. Long. 12. 35. 40. E. Lat. 45. 6. 46. N.

FOLIO, among printers and booksellers, the largest form of books, when each sheet is so printed that it may be bound up in two leaves only.

FOLKES, MARTIN, a philosopher and antiquary of considerable eminence, was born at Westminster, in the year 1690. A Mr Cappel, once professor of Hebrew at Saumur, was his private tutor. When about seventeen years of age he was sent to Clare-hall, Cambridge, where he applied himself to the study of philosophy and the mathematics; and when only twenty-three years of age he was chosen a fellow of the Royal Society. His ingenious communications acquired him so much applause that he was frequently chosen into its council. He was in habits of friendship with the illustrious Newton, at that time president; and by his influence was elected one of the vice-presidents in the year 1723. Mr Folkes became a candidate for the chair on the death of Sir Isaac Newton; but the superior interest of Sir Hans Sloane rendered his application ineffectual. In 1733, and the two subsequent years, he resided for the most part in Italy, with the view of improving himself in the knowledge of classical antiquity. To ascertain the weight and value of ancient coins, he carefully consulted the cabinets of the curious; and on his return home he presented to the Antiquarian Society, of which he was a member, a dissertation on the subject. He read before the same learned body a dissertation on the measurement of Trajan's and Antoninus' pillars, together with other remains of antiquity. The fruits of his observations he presented to the Royal Society, particularly *Remarks on the Standard Measure preserved in the Capitol of Rome*, and the model of an ancient globe in the Farnese palace. He visited Paris in 1739, where he was received with great respect, and admitted into the society of the most distinguished literary characters of that metropolis. This respect indeed he was entitled to by his unwearied application to many branches of knowledge alike curious and useful. His valuable work upon English Silver Coins was printed in the year 1745. Amongst the many honours conferred upon Mr Folkes, was that of being created doctor of laws by both universities, and chosen president of the Antiquarian Society. He continued to furnish the Philosophical Transactions with many learned papers, till his career was cut short by a paralytic stroke, which terminated his useful life in the year 1654. He was a man of extensive knowledge and approved accuracy; but the chief benefit to science which resulted from his labours was his treatise on the intricate subject of coins, weights, and measures. His cabinet and library, which were large and valuable, were exposed to public sale after his death. His private character was distinguished for politeness, generosity, and friendship.

FOLKINGHAM, a market-town of the county of Lincoln, in the hundred of Aveland and Kesteven, 107 miles from London. It is beautifully situated on the ascent of a hill, which affords a fine prospect over the plains below it. The church has a lofty tower, which is visible at a great distance. A county jail has been recently erected, and the quarter-sessions for the county are held here. The market is held on Thursday. The population amounted in 1801 to 531, in 1811 to 659, in 1821 to 759, and in 1831 to 744.

FOLKSTONE, a market-town of the county of Kent, on the sea-shore, in the hundred of its own name, of the lathe of Shepway, seventy-two miles from London. It is a member of the Cinque Ports under Dover, but returns no members to parliament. It is built on the ascent of a steep hill, the foot of which forms the sea beach. The chief employments are fishing, and the contraband trade in articles charged with heavy duties. The market is held on Thursday, and well supplied. The population amounted in 1801 to 3257, in 1811 to 3697, in 1821 to 4541, and in 1831 to 4296.

FOLKLAND, and FOLKMOTE. See FOLCLANDS and FOLCMOTE.

FOLLICULUS (from *follis*, a bag), a species of seed-vessel, first mentioned by Linnæus in his *Delineatio Plantarum*. It generally consists of one valve, which opens from bottom to top on one side, and has no suture for fastening or attaching the seeds within it.

FOLLICULI are likewise defined by the same author to be small glandular vessels distended with air, which appear on the surface of some plants, as at the foot of water-milfoil, and on the leaves of aldrovanda. In the former the leaves in question are roundish, and furnished with an appearance like two horns; in the latter, pot-shaped and semicircular.

FOLLIS anciently signified a little bag or purse, and hence it came to be used for a sum of money; nay, different sums were called by the same name. Thus the scholiast on the Basilics mentions a *follis* of copper which was worth but the twenty-fourth part of the *miliarensis*; the *glossæ nomicæ*, quoted by Gronovius and others, were, one of 125 *miliarenses*, and another of 250 denarii, which was the ancient *sestertium*; and three different sums of eight, four, and two pounds of gold were each called *follis*. According to the account of the scholiast, the ounce of silver, which contained five *miliarenses* of sixty to the pound, was worth 120 *folles* of copper. The glossographer, describing a *follis* of 250 denarii, says it was equal to 312 pounds six ounces of copper; and as the denarius of that age was the eighth part of an ounce, an ounce of silver must have been worth 120 ounces of copper; therefore the scholiast's *follis* was an ounce of copper, and equal to the glossographer's *nummus*. But as Constantine's copper money weighed a quarter of a Roman ounce, the scholiast's *follis* and the glossographer's *nummus* contained four of them, as the ancient *nummus* contained four *asses*.

FOMAHAUT, in *Astronomy*, a star of the first magnitude, in the constellation AQUARIUS.

FOMENTATION, in *Medicine*, is a fluid externally applied, usually as warm as the patient can bear it. The degree of heat should never exceed that of producing a pleasant sensation; great heat produces effects very different from those intended by the use of fomentation.

FONG-HOA-TCHING, a large, populous, and commercial town of Chinese Tartary, on the borders of Corea. It has manufactures of white and transparent paper, fabricated from cotton, which is used in windows instead of glass. Long. 143. 42. E. Lat. 40. 31. N.

FONG-TCHING, a town of China, of the third rank, in the province of Pe-tche-li. It is situated on the banks of the Grand Canal, in a fine and fertile country, and is said to be rather in a state of decay. It is twelve miles north of Kiang.

FONG-YANG, a city of China, of the first rank, in the province of Kiang-nang. It is situated on a mountain, near the Yellow River; and being the birth-place of one of the Chinese emperors, he resolved to embellish the city, and render it the seat of government. But he afterwards transferred the seat of government to Nanking, and the few works which had been completed were abandoned. This city comprehends eighteen towns under its jurisdiction. It is 340 miles south of Pekin. Long. 117. E. Lat. 32. 52. N.

FONT, among ecclesiastical writers, a large basin, in which water is kept for baptizing infants or other persons.

FONT, in the art of printing, denotes a complete assortment of letters, accents, &c. used in printing. See FOUNT.

FONTAINE, JEAN DE LA, a celebrated French poet, was born at Château-Thierry, in Champagne, on the 8th of July 1621. At the age of nineteen he entered into the congregation of the Oratory, but quitted it about eighteen months afterwards. He was twenty-two years of age before he knew his own talents for poetry; but hearing read an ode of Malherbe, upon the assassination of Henri IV., he was so seized with admiration of it, that the poetical fire, which had before lain dormant within him, seemed to be kindled from that of the other great poet. La Fontaine therefore applied himself to read, to meditate, to repeat, in fine to imitate, the works of Malherbe. The first essays of his pen he confined to one of his relations, who made him read the best Latin authors, and then the best compositions in French and Italian. He applied himself likewise to the study of the Greek authors, particularly Plato and Plutarch. Some time afterwards his parents induced him to marry a daughter of a lieutenant-general, a relation of the great Racine. This young lady, besides possessing great beauty, was remarkable for the delicacy of her wit, and La Fontaine never composed any work without consulting her. But as her temper was none of the best, the poet, to avoid dissension, separated himself from her company as often as he well could. The celebrated Duchess of Bouillon, niece of Cardinal Mazarin, being exiled to Château-Thierry, took particular notice of La Fontaine; and on her recal he followed her to Paris, where, by the interest of one of his relations, a pension was settled upon him. He met with friends and protectors amongst the most distinguished persons of the court, but Madame de la Sablière was the most prominent. She took him to live at her house; and there Fontaine, divested of domestic concerns, led a life conformable to his disposition, and cultivated an acquaintance with all the great men of the age. It was his custom, after he had fixed at Paris, to go every year, during the month of September, to his native place of Château-Thierry, and pay a visit to his wife, carrying with him Racine, Despréaux, Chapelle, or some other celebrated writers. After the death of Madame de la Sablière, he was invited into England, particularly by Madame Mazarin, and by St Evremond, who promised to secure him all the comforts of life; but the difficulty of learning the English language, and the liberality of the Duke of Burgundy, prevented his crossing the Channel.

About the end of the year 1692 he fell dangerously ill, and, as is customary upon these occasions in the Catholic church, he made a general confession of his whole life to Father Poguet of the Oratory; and, before he received the sacrament, he sent for the gentlemen of the French Academy, and in their presence declared his sincere compunction for having composed his *Tales*, a work he could not reflect upon without the greatest repentance and detestation; promising that if it should please God to restore him to health, he would employ his talents only in writing upon matters of morality or piety. He survived this illness two years, living in the most exemplary and edifying manner, and died on the 13th of March 1695, at the age of seventy-four. When his body was stripped they found next his skin a hair shirt, which gave room for the following expression of the younger Racine:

> Et l'auteur de *Jaconde* est orné d'un cilice.

La Fontaine has been justly regarded as the prince of fabulists. In his hands the apologue, which had hitherto been extremely confined, became a little poem, in which all the shades, varieties, and qualities of the other kinds of poetry were intermingled with inimitable art and simplicity. Epic poetry there recognised its recitals and its characters; dramatic poetry its actors, dialogues, and passions; didactic poetry its lessons and instruction. We there find simplicity united with vigour and dignity, and great naiveté with exquisite wit and refinement. Nothing can exceed the freshness and grace with which he paints gentle, amiable, and smiling objects; whilst, besides the other charms of the picture, the reader is agreeably surprised by those strokes of genuine comic humour in which he so greatly excelled. There is no doubt much art in all this; and it is indubitable that La Fontaine carefully elaborated his fables; but as the perfection of art is to conceal it, and simplicity is the joint result of genius and labour, so, by the union of these eminent qualities, La Fontaine, without having almost invented any thing, is nevertheless regarded as one of the most original of the French poets. He invented nothing, said Laharpe, but his style; and the secret remained with him. In imitating others he became inimitable; and he is perhaps the only poet of whom this may with truth be said. For the numerous editions of his works we must refer our readers to Brunet's *Manuel du Libraire*. The best edition of the *Fables de La Fontaine* is that of Charles Nodier, with a new literary and grammatical Commentary, Paris, 1818, in 2 vols. 8vo. Of the *Œuvres Complètes de La Fontaine* there are only four editions, all of which were published at Paris in 1813, 1814, 1817, and 1818 respectively. These editions alone contain the ballad commencing with the verse

> C'est à bon droit que l'on condamne à Rome,

and *Ragotin*, a metrical comedy, in five acts, discovered by Barbier in 1811. (See *Histoire de la Vie et des Ouvrages de M. de La Fontaine*, 1811.)

FONTAINES, Pierre-Francois Gyot Des, a French critic, the son of a councillor in the parliament of Rouen, was born in that city on the 18th December 1685, and terminated his career at Paris on the 16th December 1745. At the age of fifteen he entered into the society of the Jesuits, where he received orders; and at thirty quitted it to return to the world. He was a priest, and had a cure in Normandy, which he soon left, and, as a man of wit and letters, lived for a time with the Cardinal d'Auvergne. Having excited some attention at Paris by certain critical productions, Desfontaines was, in 1724, employed to conduct the *Journal des Sçavans.* He acquitted himself well in this department, and was peaceably enjoying the applause of the public, when his enemies, exasperated by critical strictures in his journal, caused him to be accused of an abominable crime, and procured his imprisonment. By the credit of powerful friends, however, he was set at liberty in fifteen days: the magistrate of the police took upon himself the trouble of justifying him, in a letter addressed to the Abbé Bignon; and this letter having been read amidst his fellow-labourers in the journal, he was unanimously re-established in his former credit. This happened in 1725. But with whatever reputation he acquitted himself in conducting his journal, frequent disgusts induced him at length to abandon it. Meanwhile he laboured in some new periodical works, from which he derived his greatest fame. In 1731 he commenced one under the title of *Le Nouvelliste du Parnasse, ou Refléxions sur les Ouvrages Nouveaux;* but it only extended to two volumes, the work having been suppressed by authority, from the incessant complaints of the authors ridiculed therein. About three years after, in 1735, he obtained a new privilege for a periodical production entitled *Observations sur les Ecrits Modernes*, which, after extending to thirty-three volumes, was suppressed in 1743. Yet the year following, 1744, he published another weekly paper called *Jugemens sur les Ecrits Nouveaux*, which proceeded to eleven volumes; the last two having been executed by other hands. In 1745 he was attacked with a disorder in the chest, which ended in a dropsy that proved fatal in five weeks. "He was born a sentimental person," says Fréron; "a philosopher in conduct as well as in principle; exempt from ambition; and of a noble, firm spirit, which would not submit to sue for preferments or titles. In common conversation he appeared only a common man; but when subjects of literature, or any thing out of the ordinary way, were agitated, he discovered great force of imagination and wit."

FONTANA, Felix, a distinguished physiologist and experimental philosopher, was born at Pomarolo, a little town in the Tyrol, on the 15th April 1730.

He began his studies at the neighbouring city of Roveredo, and continued them in the schools of Verona and Parma, and afterwards in the universities of Padua and Bologna. He then visited Rome, and went to Florence, where he obtained from the Emperor Francis I. who was at that time Grand Duke of Tuscany, the appointment of professor of philosophy at Pisa; but the Grand Duke Peter Leopold, who was also afterwards emperor, invited him to settle at Florence, and gave him an establishment connected with his household, as *Fisico* or naturalist, and as director of the cabinet of natural history, which was afterwards rendered by his exertions one of the principal ornaments of the city of Florence.

Fontana became the author of many well-known works on physiology, natural philosophy, and chemistry. In 1757 he was engaged in an investigation tending to confirm the doctrines of Haller respecting the irritability of the muscles, considered as a distinct quality inherent in those organs. Haller has published several of his letters as a part of his own *Mémoires sur les parties sensibles et irritables;* and the subject afforded Fontana the materials of several successive essays. 1. *De Irritabilitatis legibus nunc primum sancitis,* Atti di Sienna, vol. iii. p. 209, 1767. 2. *Ricerche filosofiche sopra la Fisica animale*, 4. Flor. 1775. This volume contains only the *Essay on the Laws of Irritability*, stating, first, the general outline of the doctrine, then entering into the different intensity of the property of irritability, and its loss by exhaustion or by inactivity, and discussing the action of the heart, and the peculiarities of the death occasioned by electricity. 3. Another link of the same chain of investigation is found in the earlier publication *De' moti dell' iride*, 8. Lucca, 1765; showing that the contraction of the pupil depends on the effect of light falling on the retina, and not on the iris itself, and establishing an analogy between the motions of the uvea, and the semi-voluntary actions of the muscles of respiration. 4. One of the most important of Fontana's works is his *Ricerche fisiche sopra 'l veneno della vipera*, Lucca, 1767; containing an immense multitude of experiments calculated to show that the poison of the viper acts by mixing with the blood, and destroying the irritability of the muscles to which it is conveyed; but that the bite of the European viper, though fatal to small animals, is scarcely ever capable of producing any immediately dangerous effects on the human frame. 5. The same matter was republished, with many additions, in the *Traité sur le Vénin de la Vipère, sur les Poisons Américains, sur le Laurier-cérise, et sur quelques autres Poisons*, Berlin, 1787; together with some observations on the primitive structure of the animal body, experiments on the reproduction of the nerves, and remarks on the anatomy of the eye. 6. In 1766 our author published an essay entitled *Nuove Osservazioni sopra i globetti rossi del sangue*, Lucca; confuting the assertions which had lately been advanced by Della Torre, respecting the complicated structure and changes of form of the globules of the blood. 7. In the next year appeared *Osservazioni sopra la ruggine del grano*, Lucca, 1767; describing an animalcule like an eel, to which he attributes the rust of coin, but which has not always been found by subsequent observers in similar cases, perhaps for want of accurate distinction. 8. There is also a *Lettre sur l'Ergot, Journ. Phys.* vii. p. 42. 9. The *Lettera sopra le Idiutidi e le Tenie, Opuscoli Scelti*. vi. p. 108, Milan, 1783, contains an account of the hydatids which produce the symptoms of vertigo in sheep. 10. A *Lettre à M.* * * *, *Journ. Phys.* vii. p. 285, contains some remarks on the circulation of the sap in plants. 11. In an essay *Sur le Tremella, Journ. Phys.* vii. p. 47, a zoophyte of a green colour, described by Adanson and others as a plant, is shown to consist of a multitude of little animals in continual motion.

12. Mr Fontana entered also very minutely, but with

more industry than accuracy or closeness of reasoning, into the chemical novelties which occupied so much attention throughout Europe in the latter half of the last century. He seems, however, to have had the merit of first applying the discoveries of Priestley respecting the effects of the nitric oxide to the examination of the qualities of the atmosphere by means of the eudiometer, which is the subject of his *Descrizione e usi di alcuni Stromenti per misurar la salubrità dell' aria*, 8. Flor. 1774, 4to, 1775, and is further illustrated in his (13.) *Recherches physiques sur la nature de l'air dephlogistiqué et de l'air nitreux*, 8. Par. 1776. He also observed the remarkable property that charcoal possesses of absorbing several times its bulk of different gases. 14. In the *Ricerche fisiche sopra l'aria fissa*, 4. Flor. 1775, he is by no means equally fortunate, having fancied that the acidity of the fixed air is not essential to it, but accidentally derived from the stronger acid employed in expelling it from the earth or alkali. 15. The *Philosophical Transactions for* 1779, p. 187, contain his *Experiments and Observations on the Inflammable Air breathed by various Animals*, consisting of a repetition of Scheele's attempt to breathe hydrogen gas, which did not always create a sensation of immediate uneasiness, though it was sometimes productive of alarming consequences. 16. In the same volume, p. 432, we find an interesting *Account of the Airs extracted from different kinds of Waters, with thoughts on the Salubrity of the Air at different places*, showing that the air afforded by water is very different under different circumstances, but that the quality of the atmosphere itself scarcely ever exhibits any variations which can be rendered sensible by chemical tests.

17. To the Memoirs of the Italian Society Fontana contributed several short essays; the first, entitled *Principi generali della solidità e della fluidità dei corpi*, vol. i. p. 89, Verona, 1782, containing the prevalent theories of the day respecting the change in the forms of aggregation of the same substance, together with experiments on the elasticity of different gases. 18. The second is a collection of definitions, entitled *Sopra la luce, la fiamma, il calore e il flogisto*, p. 104, characterizing these supposed elementary principles according to the ideas of Bergman, Scheele, and others. 19. In a later volume, v. p. 581 (1790), we find a *Lettera del Cavaliere F. Fontana al Sign. de Morveau*, in which it is conjectured that inflammable air may be a compound of phlogiston and water, and it is observed that the white crusts of flints contain as great a proportion of pure silica as their internal parts. Our author remarks, however, that his attention had of late been much distracted from chemical pursuits by the attention required for the completion of his collection of wax models of anatomical subjects, and for the duplicates which he was preparing for the cabinet of Vienna at the request of the emperor. At a subsequent period another series of copies of these models was ordered by Bonaparte to be sent to Paris; but it was there judged inferior to the preparations already existing in the Ecole de Médecine, which had been made under the direction of Laumonier, and Fontana's collection was sent to the university of Montpellier. He was latterly engaged for some time in the preparation of a colossal model of a man, built up anatomically of all his component parts, which were accurately represented in wood; but this elaborate design was never completed.

20. He was also the author of a few other chemical and mineralogical papers of less importance; for instance, of an *Analyse de la Malachite, Journ. Phys.* xi. p. 509; and, 21. A *Lettre sur du vitriol de Magnésie trouvé dans des carrières de gypse, en Piémont, Journ. Phys.* xxxiii. p. 309. 22. His last work is entitled *Principes raisonnés de la Génération.* He was also meditating an essay on the revivification of animals, but he did not live to complete it. A collection of his works, translated into French by Gibelin, was published at Paris in 1785, entitled *Observations Physiques et Chimiques.*

Fontana had become acquainted with a great number of contemporary men of science, by having travelled in various parts of Europe for the purpose of enriching the cabinet of which he was superintendent: the same official situation brought him into contact with all foreigners of distinction who passed through Florence in their travels; and he seems to have enjoyed a more extensive reputation than many philosophers of deeper research and more irresistible penetration. He wore the habit of an ecclesiastic, and was not uncommonly called abbé. He was well received in the best societies, though his manners are said to have been sometimes a little at variance with the dress which he adopted. He was treated with great respect by the French generals when they took possession of Tuscany in 1799, and hence he became the object of some suspicion upon the return of the Austrians, especially with the insurgents of Arezzo, who preceded them, and by whom he was for a short time imprisoned. His last illness was occasioned by an accidental fall in the street, on the 11th of January 1805, and he died the 9th of March 1806, at the age of seventy-five. He was buried in the church of the Holy Cross, not far from the tomb of Galileo. His Eloge was pronounced by Professor Mangili, in the university of Pavia, on the 12th November 1812. (Cuvier, in *Biographie Universelle*, vol. xv. 8. Par. 1816.) (L. L.)

FONTANA, *Gregory*, a profound mathematician and natural philosopher, younger brother of Felix Fontana, was born at Villa de Nogarola, near Roveredo, on the 7th December 1735.

He received the first rudiments of his education at Roveredo, and continued his studies at Rome, where he entered into the *Scuole Pie*, and soon distinguished himself by his talents and assiduity. He was entrusted with the care of a part of the public instruction in the school called the Collegio Nazareno, and was soon afterwards sent as a professor to Sinigaglia. It was here that he formed an intimacy with the Marquis Fagnani, whose example and assistance contributed very much to the advancement of his mathematical studies, to which he very soon in a great measure confined his attention. He was then removed by his superiors to Bologna; but his co-operation was found more necessary for the pious schools which had lately been established at Milan, and he there obtained the patronage and friendship of the Count de Firmian, the Mæcenas of the day, who greatly encouraged the publication of his first works. From these works he acquired so much credit, that he was summoned in 1763 to occupy the chair of logic and metaphysics in the university of Pavia; and he was appointed by Firmian director of the public library which he founded about the same time for the university. Two years afterwards he was advanced to the professorship of the higher mathematics, which had become vacant by the death of the celebrated Boscovich, and he filled this situation with high reputation for thirty years. He was the author of a great variety of memoirs, and did not even disdain the labour of a translator, when he thought that it could be useful to his pupils or his countrymen; but he never engaged in any single original work of great extent; for notwithstanding his habitual industry, his disposition was too volatile to allow him to confine himself long enough to any one object to effect any striking innovation in the complexion of the sciences which he cultivated. He was assiduous in the duties of his professorship; and his personal intercourse with society was extremely limited, though his correspondence with men of science was extensive. He was in the habit of writing many notes in the margin of the books that he read; and the volumes which composed his library acquired a double value from this circumstance. In April 1795 he was elected a foreign member of the Royal Society of London. About this time his health began to decline, and his physicians considered him as having suffered from too great application to his studies. In 1796 he received great marks of respect from Bonaparte, then commanding the French army in Italy; and he was made a member of the legislative body of the newly erected Cisalpine republic. In 1800, having resigned the professorship at Pavia, he came to Milan, and was afterwards nominated one of the Electoral College of the Dotti. He was still occupied in a variety of literary pursuits, when he was attacked by a violent fever, which caused his death at Milan, on the 24th August 1803. He left his manuscripts to his brother Felix, who died soon after him. An unmarried sister survived them both, and inherited the little property of her brothers, which was soon exhausted, and she was reduced to the extremity of distress. At last, finding no protection in a country to which her family had done so much honour, she became desperate, and drowned herself in the canal of Milan.

1—7. Fontana's principal publications were, first, seven Academical Dissertations on various departments of mathematical and mechanical science, among which are the *Analyseos Sublimioris Opuscula*, 4. Ven. 1763, and the *Memorie Matematiche*, 4. Pavia, 1796. 8—23. There are sixteen short memoirs in the *Atti dell' Accademia di Sienna.* Their subjects are, 8. *Astronomical Problems*, vol. v. 1774, p. 55. 9. *Theorems relating to the Integral Calculus*, p. 69. 10. *Remarks on Incommensurable Quantities*, p. 71. 11. *On the Quantity of Air in the Atmosphere*, p. 76. 12. *On the Area of a Spherical Triangle*, p. 83. 13. *On the Binomial Theorem*, p. 88. 14. *On Accelerated Motion*, p. 92. 15. *On Projectiles*, p. 97. 16. *On a Phenomenon of Vision*, p. 103, attempting to explain the comparative brightness of an object seen by one and by both eyes. 17. *On the Effect of the Solar and Lunar Attraction upon the Height of the Barometer*, p. 116. 18. *On the Mathematical Discoveries of Cardani and Cavalieri.* 19. *An Essay on the Gradual Renewal of the Blood of an Animal, and on the Principles of Compound Interest and Discount*, vol. v. 1781, p. 161. 20. *On the Axis of Equilibrium*, p. 173. 21. *On Curves described by the Centre of Gravity*, p. 177. 22. *On the Centres of Gravity of Hyperbolic Spaces or Figures*, p. 180. 23. *On Indefinite Equations, and on the Method of Indeterminates*, p. 184.

24—40. There are also a great variety of papers in the *Memorie della Società Italiana delle Scienze.* Among them we have, 24. *An Essay on the descent of a Body on a Convex Surface*, vol. i. Verona, 1782, p. 94. 25. *Remarks on the Measurement of Light*, p. 111, in which the elegant experiments of Lambert are applied to the explanation of the uniformity of the light of the sun's disk; an essay which would have saved a great Parisian astronomer some useless labour and calculation, if it had excited his attention. 26. *On the Logarithms of Negative Quantities*, p. 183. 27. *On the Equation of a Curve on Two False Theorems and on Harmonic Series*, vol. ii. 1784, p. 423. 28. *On the Pressure of Fluids*, p. 192. 29. *On Centrifugal Force*, p. 325. 30. *On Series*, p. 326. 31. *On Converging Series formed by the Products of the odd and even numbers*, vol. iii. 1786, p. 174. 32. *Analytical Researches on Refraction, on Perpetual Motion, on the Integration of Equations, on Collision, on the Resolution of Forces, and on the Pressure of Beams.* There is also an *Essay on Buffon's Combination of Mirrors*, and another *on the Quantity of Light Reflected by a Mirror in a given Direction.* 41—51. Five papers of Fontana appear in the *Memoirs of the Academy of Turin for* 1804, five in the *Biblioteca Fisica d'Europa*, and four in the *Physico-medical Journal of Pavia.* Of these, one of the most interesting relates to the *Magnifying Power of Telescopes*, and is reprinted in the fifteenth volume of the *Raccolta di Opuscoli*, published at Milan.

55. Of his translations, the principal are *La Dottrina degli azzardi di Abram Moivre*, Pavia, 1776, with additions, said to be a piratical publication. 56. *Saggio di una difesa della Divina Revelazione, di L. Eulero*, Pavia, 1777. 57. *Dissertazione di Mosheim sopra l'opera di Origene contro Celso*, Pavia, 1778, with notes. 58. *The Hydrodynamics, and other Mathematical Works of Bossut*, Sienna, 1779. 59. *Compendio di un corso di Fisica del Sign. G. Atwood*, Pavia, 1781. 60. *Saggio sopra i principi della composizione storica, del Sign. Hill*, Pavia, 1789, with an appendix. 61. *Discorso Preliminare agli atti della Società Linneana di Londra, del Sign. J. O. Smith*, Pavia, 1792. 62. *Sermone sul Martirio del re Carlo I. dal Dr G. Swift*, Pavia, 1798. 63. *L'Esempio della Francia, avviso e specchio all' Inghilterra, di A. Young*, Pavia, 1794. (Guillion *in Biographie Universelle*, vol. xv. Paris, 1816.) (L. L.)

FONTENAY, an arrondissement of the department of Vendée, in France, extending 1116 square miles. It is divided into eleven cantons, and subdivided into 161 communes, and contains 117,524 houses. The capital is a city called Fontenay Le Comte, situated in a valley through which the Vendée runs. It is an ill-built, old-fashioned town, distinguished only by its lofty tower on the mother church, which is 294 feet in height, and very beautiful. It contains 1485 houses, and 6615 inhabitants. It has some trade in linen and woollen goods. It has not yet recovered from the effects of the revolution. Long. 2. 3. W. Lat. 36. 40. N.

FONTENELLE, BERNARD LE BOVIER DE, was born at Rouen on the 11th February 1657, and died at Paris on the 9th January 1757. It was during this interval of time, comprehending an entire century, that the greatest writers France has produced commenced or terminated their career; and amongst these illustrious men, who were all either the friends, the enemies, or the rivals of Fontenelle, none was more remarkable whilst living, or has been more celebrated since his death. For this advantage he has been principally indebted to the variety of his acquirements, the fineness of his genius, and the versatility and grace of a talent peculiarly French, which seems to have acquired its greatest perfection, and displayed itself in the happiest manner, in the country which gave him birth, and in the age when he flourished. Fontenelle received his education in the college of Jesuits at Rouen, where the quickness and aptitude of his powers became conspicuous at a very early period. When only thirteen years of age he commenced the study of rhetoric; and so rapid was his progress, that in a note opposite his name on the register of the college, he is described as *adolescens omnibus partibus absolutus, et inter discipulos princeps.* At the desire of his father he studied the law; but as he lost the very first cause in which he was employed as an advocate, he became disgusted with his profession, and devoted himself entirely to literature and philosophy. He composed a considerable part of the operas of *Psyche* and *Bellerophon*, which were printed under the name of his uncle Thomas Corneille; and he also wrote a tragedy called *Aspar*, but as it did not succeed, he consigned the manuscript to the flames, and never afterwards attempted that species of composition. His *Dialogues des Morts* were published in the year 1683, and well received as a specimen of elegant composition, combining morality with the charms of literature; in fact, this work laid the foundation of the great reputation of Fontenelle. His *Lettres du Chevalier d'Her*, published in 1685, without his name, discovered much wit and ingenuity, but at the same time no small share of affectation, and obtained only moderate success. But his *Entretiens sur la Pluralité des Mondes* has been regarded as one of his ablest performances, combining science and philosophy with vivacity and humour, a talent which may be said to belong almost exclusively to the French nation. It was universally read, and translated into several foreign languages. In his *Histoire des Oracles* he supported the opinion that oracles were forgeries, in opposition to those who contended that they were supernatural operations of evil spirits, put to silence by the appearance of Christ, and consequently exposed himself to much clerical animadversion. Le Tellier denounced the book, and the Jesuit Baltus attempted to refute it; whilst others, again, wrote as warmly in its defence, contending that the opinion therein maintained was conformable to that of the most renowned theologians. Fontenelle took no part in the dispute, but contented himself with writing to M. Leclerc, "It belongs rather to M. Van-Daale than to me to answer on this occasion; he is my guarantee, I am only his interpreter; and I have no objection that the Devil should be a prophet since the Father Jesuit wishes it so, and considers it the more orthodox opinion." His Pastoral Poems, which appeared in the year 1688, with a discourse on the nature of the eclogue, were very much admired for their delicacy of sentiment, as was also his opera of Thetis and Peleus; but his Æneas and Lavinia was not so successful. In the year 1699 Fontenelle was chosen secretary of the Academy of Sciences, which office he held during the long period of forty-two years. Whilst in this office he published annually a volume of the history of that learned body, entitled *Histoire de l'Académie des Sciences,* filled with analyses of memoirs, and éloges on deceased members. Besides his labours as secretary, he also made his contribution as an academician, by composing his *Géométrie de l'Infini,* a work of which he jocularly observed that there were only eight men in Europe in a condition to understand it, and that the author was not one of the number. It appears, however, that Fontenelle was by no means profound in the mathematics; and hence, with the exception of a preface to the *Analyse des Infiniments Petits* of L'Hôpital, and a memoir on the extension of the property of the number *nine,* he produced no other works on the subject. As a poet, Fontenelle did not rise above elegance and ingenuity; as a man of science, he excelled in throwing light on the inventions of others, rather than in discovering new truths himself; and as a general writer, he united solid sense with the delicacy and refinement of a man of wit. He studied his own comfort as much as most men, but never sacrificed to selfish gratification the duties of a man of honour and of virtue. He had many friends, and towards the close of his life scarcely a single enemy. He was never married, and, for a man of letters, had acquired considerable affluence. Although of a delicate constitution, he reached the age of ninety without any complaint except deafness; and died, as already mentioned, on the 9th of January 1757, being within a few days of a hundred years of age. When asked by a certain person how he could pass so easily through the world, he replied, by virtue of two axioms, namely, that all is possible, and that every one is in the right.

There are only two complete editions of the works of Fontenelle; one in eleven volumes 12mo, Paris, 1758, 1760; and the other in eight volumes 8vo, Paris, Bastien, 1790. In these editions are found the Prefaces and Eloges which form part of the History of the Academy of Sciences; but they contain neither the Analyses nor the *Géométrie de l'Iufini,* which first appeared in 1727, 4to. The edition of the *Œuvres Diverses,* published at the Hague, 1728, 1729, is much sought after on account of the engravings of Bernard Picard. But the work of Fontenelle which has been most frequently reprinted is his *Entretien sur la Pluralité des Mondes.* The first edition appeared in the year 1686; but the sixth conversation, composed long afterwards, was only printed in the edition of 1719. The principal other editions are that of Dijon, Causse, 1793, in 8vo; that of Didot, 1796, in 4to; and that printed in 1800, with the notes of Lalande, which is the best. In 1730 there appeared at Leipsic, in 8vo, a German translation by Gottsched; in 1751, an Italian translation by Vestrini, published at Arezzo; and there are three English translations, the best of which was published in 1760, in 8vo.

FONTENOY, a village of the Netherlands, in the province of Hennegau, and circle of Tournay, containing 580 inhabitants. It is memorable for the battle fought there in 1745, in which the allies commanded by the Duke of Cumberland were defeated by the French under Marshal Saxe.

FONTEVRAUD, or FONTEVRAUX, *Order of,* in *Ecclesiastical History,* a religious order, instituted about the latter end of the eleventh century, and taken under the protection of the holy see by Pope Pascal II. in 1106, confirmed by a bull in 1113, and invested by his successors with very extraordinary privileges. The chief of this order was a female, appointed to inspect both the monks and nuns. The order was divided into four provinces, which were those of France, Aquitaine, Auvergne, and Bretagne, in each of which they had formerly several priories.

FONTINALIA, or FRONTANALIA, in *Antiquity,* a religious feast held amongst the Romans in honour of the deities who presided over fountains or springs. Varro observes that it was the custom to visit the wells on certain days, and to cast crowns into fountains. Scaliger, in his conjectures on Varro, supposes that this was not a feast of fountains in general, as Festus insinuates, but of the fountain which had a temple at Rome, near the Porta Capena, called also *Porta Fontinalis;* and he adds, that it is of this fountain Cicero speaks in his second book *De Legibus.* The Fontinalia were celebrated on the 13th of October.

FOOD.

OUR observations upon this subject may be conveniently arranged as relating to the *Selection, Preservation,* and *Preparation* of the various substances which are commonly used for food.

SELECTION.

General observations.

Animal matters in general are safe articles of food. In regard to the higher classes, the mammalia and birds, this is universally true of those in a state of health. A few exceptions occur among the fishes, depending either upon the constitution of certain persons, who are injuriously affected by substances generally alimentary, or upon some singularity in the nature of the individual fish, by which it becomes poisonous, although the species is generally nutritious and wholesome. As we descend still lower in the scale, these exceptions occur more frequently, and more species are absolutely and universally unwholesome, or furnish poisons hurtful to every constitution. In the vegetable kingdom, the alimentary vegetables form but a small proportion of the whole, and almost an equal number are absolutely poisonous, or at least injurious, except when

Quadru peds.

given in small quantities, to counteract some existing disease.

Although quadrupeds, without exception, furnish articles which may be safely used as food, their flesh differs much in palatability, and probably in its nutritious qualities. There is also no part of this class of animals that may not be, and indeed is not occasionally used as food, although the flesh, or voluntary muscles upon the limbs, trunk, and head, is by far the most considerable and important. The heart, the largest of the involuntary muscles, is also commonly eaten; and the brain and spinal marrow or pith; all the glands, the kidneys, liver, udder, and sweetbread; the compound internal organs, the lungs, stomach, and intestines, the uterus, placenta, and even the contents of the stomach, the fat and marrow of the bones, the blood and skin, are all nutritious, and some of them highly prized; and even the bones themselves can be made to furnish much wholesome nutriment. The milk of all quadrupeds is also alimentary, and generally agreeable.

These various organs, although each of them contains several immediate principles, considered chemically, are characterized by some difference in their composition. The muscular flesh consists principally of fibrine, combined with some gelatinous mucus and osmazome; the tendons of the muscles, on the contrary, are little else than gelatine in a very dense form. This is likewise the case with the skin, the membranes in general, and the ligaments. Brain and medullary nervous matter consist chiefly of coagulated albumen, which also, perhaps, enters largely into the composition of glands. The fat, suet, and marrow of the bones, are different forms of concrete animal oil. All these principles are digestible and nutritious, but in what comparative degree is far from being ascertained. According to popular opinion, it is nearly inversely as their solubility in water, muscular flesh being considered to furnish the strongest aliment, and gelatinous organs the lightest. But these substances are not exactly similar in all animals, nor even in the same animal at different periods of life.

Size.

In general the flesh and other parts are coarser in proportion to the size of the animal, not only when different in kind, but in different varieties of the same species, although well-grown individuals of the same variety are always better than those which have not been sufficiently nourished. Thus the flesh of the elephant and rhinoceros have been found to be very coarse and unpalatable, whilst that of the rat and smaller quadrupeds is very delicate. The larger varieties of the ox and sheep, also, are inferior to the smaller, as the kyloes of the Western Islands, and the sheep of Wales and the Highlands of Scotland.

The whole organs of young animals are much more gelatinous than those of the adult and aged, whilst these contain more fibrine and extract. Hence the flesh of young animals is more bland and tender, and yields most to the action of boiling water; whilst that of aged animals is more savoury, even to rankness, and is firm to toughness.

The flesh of very young animals is to our palates unpleasantly soft and flabby, qualities of which every one is a judge; but it is at no period of life, not even in the fœtal state, actually unwholesome; and therefore there was no rational ground for that enactment which provided that no butcher shall kill any calf to sell being under five weeks old. The fact is, that cows large with calf are frequently killed, and the fœtus is always sold as very young veal, and preferred by some people. By our butchers, calves are killed at from six to sixteen weeks; but they are reckoned best at ten or twelve. Lambs are generally killed at from eight weeks to half a year.

The flesh of quadrupeds in the vigour of life is more stringy, and again becomes shorter as it advances to old age, when it becomes dry and unnutritious. Young animals also differ from those that are aged, in the distribution of the fat, which in the latter is chiefly collected in masses or layers external to the muscles, and in the former is more interspersed among the muscular fibres, giving the flesh a marbled appearance, which is always a desirable property in butcher-meat.

The beef of the larger breeds of oxen is in perfection when the animal is about seven years old, that of the smaller breeds a year or two sooner. Cow beef, on the contrary, can scarcely be too young. The flesh of a young heifer is highly esteemed; that of an old fattened cow is very bad. Wedder mutton is in perfection at five years. Ewe mutton is best when about two years old. Sucking pigs are killed about three weeks old; but pork differs from other kinds of butcher-meat in not requiring age to mellow it; so that swine for pork are killed at from six to twelve months old; but for brawn, age is an advantage, or rather necessary. The buck of the fallow-deer may be killed at six, but is better at eight years of age. The female in general being naturally more tender, and getting tough rather than mellowing by age, is sooner in perfection.

Sex.

The sex also greatly influences the quality of the flesh, that of the female being always more delicate and finely grained than that of the entire male, of which the fibres are stronger and the taste more rank. Indeed the influence of the genital organs on the flesh of animals is very remarkable. The delicacy of the flesh, even of the female, is greatly improved by removing the ovaries, or "spaying" them as it is called. Every day the testes are permitted to remain, even though totally inactive as to their proper function, injures the delicacy of the veal of the bull-calf; and an animal which is not castrated until after puberty always retains much of the rankness and coarseness of the entire male. Daubenton[1] directs that the male lambs should be castrated at from eight to fifteen days after their birth, although it is not usual to perform the operation until the age of three weeks, or even five or six months. But their flesh is never so good as when they are castrated at eight days. Huzard goes farther, and recommends it to be performed in a day or two after their birth, or as soon as the testes descend into the scrotum. The female lambs are also spayed occasionally in France, to render their flesh more delicate, and to improve the wool; but the operation cannot be performed until the ovaries have acquired a sufficient size to be brought out with the finger, when about three weeks old. In this country the sow pigs which are not reserved for breeding are all spayed when about four weeks old; the boar pigs are castrated a week sooner. On the other hand, the males of those races in which the testes are active only at certain seasons, as the deer tribe, have the coarse rank flesh of entire males only when rutting, and at all other times they much more resemble the castrated individuals of those animals, such as the bull, which are always capable of procreating their species. Even with the ram there is a short period when the flesh is less rank, and during the rutting season it is intolerable. Buck venison is highly esteemed, and the boar is preferred for making brawn.

Food.

The manner in which the animal has been fed has also considerable influence on the quality of the flesh. Generally the lean of fat animals is better than that of those that are poor, and perhaps an animal in a state of nature can never be too fat. Artificial fattening may, however, be carried too far; and the practice of feeding oxen

---

Selection of Food.

on oil-cake for the market is now almost laid aside, as the beef acquires from it an unpleasant rancidity. Also unwholesome fatness, such as that which takes place in the first stage of the rot, and which, it is said upon very good authority, some butchers induce artificially, is certainly not desirable. “ Several graziers and butchers having observed that sheep are much disposed to feed during the first stage, or four weeks after being tainted, omit no opportunity of producing it to increase their profits.”[1] But it is not only in regard to fatness that the flesh of animals is affected by the nature of their food, for its flavour is materially altered by it, and an epicure will readily distinguish by the taste, whether mutton of the same race has been fed upon turnips, or upon the natural grasses of a Highland farm.

The effect of the food is more apparent in pork than in any other kind of butcher-meat. The fat of pigs fed on skimmed milk, though sour, is firmer, and vastly superior to that of hogs fed upon peas or meal. And Mr Jackson says we have no pork in England or Ireland equal to that of Sardinia, where the hogs are almost wild, and fattened upon chestnuts.

Season.

The season of the year has considerable influence on the quality of butcher-meat, though less than upon other kinds of aliment. Its influence depends upon the more or less plentiful supply of food, upon the periodical change which takes place in the body of the animal, and upon temperature. *In season* and *out of season* are words often vaguely applied, meaning, most commonly and correctly, the period of the year in which the substance in question is naturally best and worst, but also occasionally expressing the good or bad condition of the individual animal, without any regard to the state of the species in general; and lastly and most improperly, meaning that it is at that time desired or rejected by the higher classes of society as being rare or common. The flesh of most full-grown quadrupeds is in highest season during the first months of winter, after having enjoyed the advantage of the abundance of fresh summer food. Its flavour then begins to be injured by the turnips given as winter food, and in spring it gets lean from deficiency of food. Although beef and mutton are never absolutely out of season, or unfit for the table, they are best in November, December, and January. Pork is absolutely bad or out of season during the summer months, and is only good in those of winter. The males of the deer tribe are in highest season from the middle of June to the beginning of September, when they begin to rut, after which they become thin and exhausted. Females in general are out of condition when they are suckling, or have lately suckled or given milk. Does which have had no kids, or were soon deprived of them, follow the general rule of castrated animals, and are in season from the middle of November to the middle of February. Their condition is not much affected during the first months of pregnancy. The season of the year when the young of quadrupeds have acquired the proper age for being used as aliment is the period when they are in season. This is naturally in the summer months, when lamb, veal, kid, and fawns are most abundant. But breeders continue to furnish the tables of the wealthy with the first two of these at almost every season of the year, by selecting certain breeds, such as the Dorsetshire sheep, which lamb very early, or by treating them in such a way as to cause the female to come in heat at an unnatural time. In this way lamb is procured as an article of luxury as early as November and December; and, on the contrary, by keeping the ewe on a cold and poor hill pasture, the lambing season is retarded.

Mode of killing.

The mode of killing has considerable effect on the flesh of the animal. Most of those slaughtered for food are either bled to death, or are bled profusely immediately after being deprived of life in some other way.

The common mode of killing cattle in this kingdom is by striking them on the forehead with a pole-axe, and then cutting their throats to bleed them. But this method is cruel, and not free from danger. The animal is not always brought down by the first blow, and the repetition is difficult and uncertain; and if the animal be not very well secured, accidents may happen. Lord Somerville,[2] therefore, endeavoured to introduce the method of pithing or laying cattle, by dividing the spinal marrow above the origin of the phrenic nerves, as is commonly practised in Barbary, Spain, Portugal, Jamaica, and in some parts of England; and Mr Jackson says, that “ the best method of killing a bullock is by thrusting a sharp-pointed knife into the spinal marrow, when the bullock will immediately fall without any struggle; then cut the arteries about the heart.”[3] Although the operation of pithing is not so difficult but it may, after some practice, be performed with tolerable certainty, and although Lord Somerville took a man with him to Portugal to be instructed in the method, and made it a condition that the prize cattle should be pithed instead of being knocked down, still pithing is not becoming general in Britain. This may be partly owing to prejudice; but we have been told that the flesh of the cattle killed in this way in Portugal is very dark, and becomes soon putrid, probably from the animal not bleeding well, in consequence of the action of the heart being interrupted before the vessels of the neck are divided. It therefore seems preferable to bleed the animal to death directly, as is practised by the Jew butchers.

The Mosaic law so strictly prohibits the eating of blood, that the Talmud contains a body of regulations concerning the killing of animals; and the Jews, as a point of religion, will not eat the flesh of any animal not killed by a butcher of their own persuasion. Their method is to tie all the four feet of the animal together, bring it to the ground, and, turning its head back, to cut the throat at once down to the bone with a long, very sharp, but not pointed knife, dividing all the large vessels of the neck. In this way the blood is discharged quickly and completely. The effect is indeed said to be so obvious, that some Christians will eat no meat but what has been killed by a Jew butcher.

Calves, pigs, sheep, and lambs, are all killed by dividing at once the large vessels of the neck. Animals which are killed by accident, as by being drowned, hanged, or frozen, or by a fall or ravenous animal, are not absolutely unwholesome. Indeed they only differ from those killed methodically in not being bled, which is also the case with animals that are snared, and in those killed by hounds. Animals which die a natural death should never be eaten, as there are undeniable instances of disease, and even death, being the consequence.

Animals frequently undergo some preparation before they are killed. They are commonly kept without food for some time, as, if killed with full stomachs, their flesh is considered not to keep well. Oxen are commonly fasted two or three days, smaller animals a day; but it is evident that the practice must not be carried too far, as the opposite effect will be produced by the animal falling off or getting feverish. It is generally understood that, in order to have veal very white, the calf is repeatedly bled largely before it is killed. But the practice does not seem to be very common. It is altogether denied by the feeders, and not confessed by the butchers. We are not, therefore, able to say what its effects would be; but Dr Lister has stated that nothing contributes more to the whiteness and tenderness of the flesh of calves than often bleeding them, by which the colouring matter of the blood is exhausted, and nothing but colourless serum remains. A much more cruel method of preparation for slaughter used to be practised, though now much less frequently, in regard to the bull. By some ancient municipal laws, no butcher was allowed to expose any bull-beef for sale, unless it had been previously baited. The reason of this regulation probably was, that baiting had the effect of rendering the flesh or muscular fibre much more tender; for it is a universal law of the animal economy that, when animals have undergone excessive fatigue immediately before death, or have suffered from a lingering death, their flesh, though it becomes sooner rigid, also becomes sooner tender than when suddenly deprived of life in a state of health. The flesh of hunted animals also is soon tender and soon spoils;[1] and it is upon this principle only that the quality of pigs' flesh could be improved by the horrid cruelty, said to be practised by the Germans, of whipping the animal to death. Another part of the same receipt, to roast a pig wild-boar fashion, consists in making him swallow, some hours before death, a quantity of vinegar aromatised with herbs. We notice this, because we think the action of vinegar given to animals some hours before death, in rendering the fibre mellow, deserves to be examined. It is a common practice in the country to give poultry a spoonful or two of vinegar some time before they are killed, when they are to be dressed immediately. Popular practices are seldom without some foundation, and with this, the fact that acetic acid or vinegar has a peculiar chemical action upon fibrine connects itself. The Moors in West Barbary, before they kill a hedgehog, which is esteemed a princely dish among them, "rub his back against the ground, by holding his feet betwixt two, as men do a saw that saws stones, till it has done squeaking, and then they cut its throat." (Mr Jones, *Phil. Trans.* No. 254.)

Birds.

There is no bird, and no part of any bird, nor any bird's egg, which may not be safely used as food. Gmelin quotes a singular instance of some persons having been much affected after eating larks; and suspects that the flesh of the birds may have been rendered poisonous by their having fed upon hemlock-seed, which they eat with impunity. But there can be no doubt that this must be a mistake, for larks are a common and favourite food in the very country where this accident is said to have happened.

The flesh of birds differs very much in its sensible properties, not only in different kinds, but even in the different muscles of the same bird. The pectoral muscles which move the wings are whiter, drier, and more tender than those which move the legs. The tendons of the legs are also very strong, and at a certain age become bony; but the flesh of the legs, when sufficiently tender, either from the bird being young, or from long keeping, or sufficient cookery, is more juicy and savoury than that of the wings. Of a few birds, especially the woodcock and snipe, the legs are at all times preferred to the breast. In the black-cock, the outer layer of the pectoral muscles is of a dark-brown colour, while the inner is white. A similar difference is observed in many other birds, and perhaps it is general in a slight degree. The muscular organs of birds differ from those of quadrupeds in their flesh never being marbled, or having fat mixed with the muscular fibres.

There is a great diversity in the flesh of the different classes of birds; but no very accurate distribution of them in this respect can be made, as, though the extremes are sufficiently marked, they run insensibly into each other. We may, however, notice, as sufficiently distinct, 1. the white-fleshed, exemplified in the common fowl and turkey; 2. dark-fleshed, game, grouse, black-cock; 3. aquatic, goose, duck; and, 4. rapacious, hawks and owls. Several species of the first and third classes are domesticated, and reared in great numbers as esteemed articles of food. The white-fleshed birds are very generally liked, when good of their kind, and by many are preferred to game, which, however, when sufficiently kept, is one of the greatest luxuries of an epicure's table. It has then acquired a peculiar odour, called *fumet*, and an aromatic bitter taste, most sensible in the back. The aquatic birds, both swimmers and waders, are generally eaten, and many of them are very delicate; but in general they are disposed to become very fat, and often acquire a rancid and fishy taste. This is chiefly connected with the fat, and may be somewhat avoided by skinning the bird, and removing the inside fat, before cooking. Of the rapacious birds none are eaten, partly perhaps from prejudice, and partly because those which touch carrion acquire a cadaverous smell.

The muscular fibre is coarser in the larger than in the smaller birds of the same class, and it becomes less tender as they get older. It is also much influenced by sex, although of some birds the young cock is preferred, chiefly, we apprehend, on account of its greater size and handsome appearance. By removing the sexual organs at an early age, both sexes are much improved for the use of the table, becoming larger, fatter, and more tender, as we see in the capon and poulard. The manner in which birds are fed affects both their fatness and their flavour. Birds seldom get very fat in their wild state, or when domesticated, if allowed to go at large. The art of fattening poultry consists in supplying them with abundance of healthy food, and confining them. Aquatic birds, ducks and geese in particular, must be prevented from going into the water, both because they never get fat, but also acquire a rancid fishy taste.

Modes of fattening.

The fattening of fowls for the London market is a considerable branch of rural economy in some convenient situations. "They are put up in a dark place, and *crammed* with a paste made of barley-meal, mutton-suet, and some treacle or coarse sugar, mixed with milk, and are found to be completely ripe in a fortnight. If kept longer, the fever that is induced by this continued state of repletion renders them red and unsaleable, and frequently kills them."[2] But fowls brought to this state of artificial obesity are never so well flavoured in the flesh, and probably not so salubrious, as those of the same species fattened in a more natural way. The great secret of having fine pullets is cleanliness, and high keeping with the best corn.

Epicures in all ages have been exceedingly whimsical in the selection of certain parts of particular birds as dainties, and the ancients more so than the moderns; for although we still prize the combs of the common fowl, the trail of the woodcock, and even collect with care the dreg which drops from it in the process of roasting, the guts of the bustard, the gizzard and liver of the goose, and the feet of the duck; we find that Roman epicures delighted in the brains of ostriches and parrots, the tongue of the flamingo, and the enlarged liver of the goose. The last still continues among our continental neighbours to be in great request, and the providing them is a considerable branch of rural economy in some provinces. It is said that, at Strasburg, it is effected by actually sewing up the anus of the tortured animal, after a certain preparation; but we have not met with the barbarity set down in print, and it is perhaps not true, otherwise so striking an exemplification of Sir E. Home's doctrine, that the fatness of animals depended upon the length of their intestinal canal, and the length of time the fæces were retained in it, would not have escaped his notice. The process followed in different parts of France is described at length by Sonnini:[1] "The object of the third method is to enlarge the liver. Nobody is ignorant of the endeavours of sensuality to cause the whole vital forces to be determined towards this part of the animal, by giving it a kind of hepatic cachexy. In Alsace, the individual buys a lean goose, which he shuts up in a small box of fir, so tight that it cannot turn in it. The bottom is furnished with a wide grating of rods, for the passage of the dung. In the fore part there is a hole for the head, and below it a small trough is kept always full of water, in which some pieces of wood charcoal are left to steep. A bushel of maize is sufficient to feed it during a month, at the end of which time the goose is sufficiently fattened. A thirtieth part is soaked in water each night, and crammed down its throat next day, morning and evening. The rest of the time it drinks and guggles in the water. Towards the twenty-second day they mix with the maize some poppy oil, and at the end of the month it is known by a lump of fat under each wing, or rather by the difficulty of breathing, that it is time to kill it, otherwise it will die of fat. The liver is then found weighing one or two pounds, and besides, the animal is excellent for the table, and furnishes, during its roasting, from three to five pounds of fat, which is used in the cookery of vegetables. Of six geese, there are commonly only four, and these are the youngest, which answer the expectation of the fattener. They are kept in a cellar, or place with little light; and the Roman epicures, who prized their livers, had already observed, that darkness was favourable to this kind of education, no doubt because it prevents all distraction, and directs the whole powers towards the digestive organs. The want of motion, and the difficulty of respiration, may be also taken into consideration; the first by diminishing the waste of the system, and both by retarding the circulation in the vena portarum, of which the blood ought to become hydrogenated, in proportion as its carbon unites itself to the oxygen, which that liquid absorbe. This favours the formation of the oily juice, which, after having filled the cellular system of the body, enters into the biliary system and substance of the liver, and gives it that fatness and size which is so delightful to the palates of true gourmands. The liver thus only becomes enlarged consecutively, and the difficulty of respiration does not appear till the end, when its size prevents the action of the diaphragm."

---

[1] *Recherches de Physiologie et de Chimie Pathologique.* Par P. N. Nysten, 8vo. Paris, 1811.

[2] *Agricultural Report of Berkshire.* By William Mavor, LL. D. 8vo. London, 1813.

"The leanness of geese subjected to this treatment is often mentioned; but it can only occur in those whose eyes are put out, and feet nailed down to a board, as the consequence of this barbarous treatment. Among a hundred fatteners, there are scarcely two who adopt this practice, and even these do not put out their eyes till a day or two before they are killed. And therefore the geese of Alsace, which are free from these cruel operations, acquire a prodigious fatness, which may be called an oleaginous dropsy, the effect of a general atony of the absorbents, caused by want of exercise, combined with succulent food crammed down their throats, and in an under oxygenated atmosphere."

There are certain months in which each kind of bird is considered to be in season, and which are determined by the time of their breeding, the abundance of food, or their migration. Some birds do not remain with us all the year, and are therefore to be valued when we can get them. The migrating birds go farther south in winter, and north in summer. They are, therefore, with us in winter or summer, according to their habits in regard to temperature and the supply of food. Those birds which remain during summer breed here, and their young may be obtained before they fly, and whilst they are still delicate, as the gannet or solan goose; others, as the woodcock, rarely breed in this country, and are only got in their adult state.

There is but little diversity in the mode of killing birds. Game is almost always shot, as hawking is entirely out of fashion, although formerly birds killed in this way were more esteemed, as, indeed, their flesh would be sooner tender. Larks are caught in winter in traps and nets, and then killed. The heads are twisted off young pigeons; but domestic birds, in general, are killed in a very unskilful and barbarous manner. The common fowl has its neck drawn, by which the spine is torn asunder at an uncertain place; and if the spinal cord be not divided, or be divided too low, the animal dies slowly, and is sometimes alive after its feathers have been plucked off. The large blood-vessels are sometimes also torn across. This is an advantage, both from shortening the sufferings of the animal, and rendering its flesh whiter in consequence of the loss of blood. Turkeys are bled to death by dividing the vessels under the tongue. The only objection to this is that it is tedious, for probably it is not attended with much pain. Geese are killed by splitting the skull with a knife. This is sometimes very awkwardly performed, and neither any large vessels are divided, nor the nervous energy destroyed. Domestic birds are generally kept confined and fed upon choice food for some time before they are killed, and sometimes they are crammed, or forced to eat more than they would voluntarily. They should always be kept a day without food at the last, that their crops may be empty, as food left in them is apt to taint the flesh.

Of the reptiles, very few are used as food, though probably rather on account of their disgusting appearance, than of their being hurtful, or even unpalatable, as some of the greatest luxuries of the table belong to this class of animals. Besides the green turtle, several other species of *Testudo* are eaten, especially the *Græca*, *Europæa*, and *ferox*. Of the lizards, the *Dracæna*, *Amboinensis*, *agilis*, and *Iguana*, are eaten. The flesh of the last is said to be delicious, but unwholesome, especially to those persons affected with syphilis, which, however, is probably a vulgar prejudice. The *Lacerta scincus* is held in estimation by the natives of the east as aphrodisiac. The eggs of the *Iguana* and of most species of *Testudo*, even of those whose flesh is said to be bad, as of the *Imbricata*, are nutritious and agreeable. The flesh of the *Coluber natrix* is eaten in some places; and even the viper, whose bite is poisonous, furnishes a nutritious broth to invalids. Of the frogs, the *Rana esculenta* is a favourite article of food with our continental neighbours. The *Rana taurina*, or bull-frog, rivals the turtle in the opinion of our Transatlantic descendants. The *Rana bombina*, though a toad, is also eaten in some places as a fish. We have no doubt that many other reptiles are used as food in some countries; and we are not aware of a single instance where injurious effects have been produced by any that have been tried. Their flesh seems in general to be delicate and gelatinous; the fibre resembles that of chicken or veal; and what is called the green fat of turtle is in reality

---

[1] *Nouveau Dictionnaire d'Histoire Naturelle*, art. *Oie.*

Selection of Food.

gelatinous, like the skin of calf's head, or the tendons of ox-heel, which are employed to make an imitation of it. We know little of the circumstances which influence the quality of reptiles as esculent; but the modern Apicius says, the best size of a turtle for taste is sixty pounds to eighty pounds, which is scarcely a tenth part of the size they sometimes reach; and we may presume that, like most other oviparous animals, they are best before they begin to lay their eggs, and out of season for some time afterwards. Turtles often become emaciated and sickly before they reach this country, in which case the soup would be incomparably improved by leaving out the turtle, and substituting a good calf's head.

In some places fish constitutes the sole or chief food of the people, hence called Ichthyophagi, and almost everywhere it is in request. In Siberia, dried fish is used instead of bread. The Laplanders make a bread of fish bones, and the Negroes of the western coast of Africa dry a species of sprat, and beat it in wooden mortars to a paste, which keeps all the year, and is eaten with rice or corn. Putrid fish is even the favourite and ordinary food of some tribes. Fish, however, is not so universally a safe aliment as the two preceding classes of animals; for although no species is generally unwholesome, yet, in some situations, individuals of many different species are absolutely poisonous, whilst others of the same species, and not to be distinguished by any certain external characters, at the same place, and in the same season, are innocent and nutritious, which render the eating of fish in such countries not free of danger.

Pois ous fish.

The subject of poisonous fishes is still involved in great obscurity, although so important to those who are exposed to suffer from them. It is not peculiar to any genus, species, or distinct variety, but occurs in individuals only, and those of several genera of very different classes, such as *Clupea, Perca, Boracinus, Sparus, Coryphœna, Scomber, Murœna, Balistes, Tetrodon*, and *Cancer*. Except the *Bogmarus Islandicus*, which is reputed poisonous by the Icelanders, because the crows refuse to eat it, poisonous fish occur chiefly in tropical seas. It is only at certain seasons, however, that any poisonous fish occur; as in the Carribbean Sea in May, June, and July, after having spawned. Their deleterious effects are ascribed by some to the fish feeding on poisonous substances, as on copper banks, medusæ, and holothuriæ, or the manchineel apple. The poison is supposed to exist in the gall; and it is said that if the peritoneum and all the entrails be speedily and dexterously removed, the flesh may always be eaten without danger. A fish is suspected when it is of an unusually large size, or is destitute of the natural fishy smell, or has black teeth, or when silver or an onion boiled along with it becomes black; but all these tests are uncertain. The poisonous quality is also said to be destroyed by salting the fish, or drinking along with it sea water, or the ripe juice of the lime, sugar cane, or sweet potato.

Some ancient, as well as modern naturalists and physicians, consider the roe of the barbel as unwholesome when eaten; others think it is hurtful only at certain seasons to certain individuals, and when eaten in excess; and, lastly, some declare the whole allegations to be erroneous and unfounded. Bloch, the great ichthyologist, and Bosc, both assert that they and others have eaten it without any inconvenience; but Dr Crevelt of Bonn has published cases which leave little doubt that in some cases the roe is actually injurious, although the flesh of the same individual was eaten with impunity.

The ancients had many prejudices in regard to the wholesomeness or unwholesomeness of certain fishes. The Egyptian priests were forbidden to eat fish of any kind, under the idea that it increased the sexual appetite, or that it was a cause of the leprosy. For the latter reason the people were forbidden to eat any fish not covered with scales. Moses adopted the same principle: "Whatsoever hath fins and scales in the waters, in the seas, and in the rivers, them shall ye eat." "Whatsoever hath no fins or scales in the waters, that shall be an abomination unto you."[1] Numa made a law for the Romans much to the same effect; but it did not continue in force, as we find the lamprey and sturgeon among the luxuries of the emperors; and such fish now form the chief support of the people in some districts, without being followed by any bad effect.

Fishes, however, present an infinite variety in regard to their fitness as articles of food, in the colour and texture of their muscles, and in being more or less gelatinous, fibrous, or oily. The muscles of many fish, with the exception of the heart, are quite white, and in general, when the fish is good, they become opaque when cooked. When they remain semitransparent and bluish after sufficient boiling, they are not in season. Of some fishes the flesh is a pale red at certain seasons, and the higher the colour of these kinds the more are they esteemed. Of most fishes the muscles are disposed in flakes, and when in perfection, there is, when cooked, a layer of white curdy matter between them, resembling coagulated albumen. Some other fishes, chiefly those that are flat, or eel-shaped, or without scales, have a fibrous flesh, not divisible into flakes. The liver of the fish tribe abounds with oil, and of many species the flesh is mixed or covered with oil or fat, as the eel or salmon; but of many others the flesh seems to be totally free from it, as all the varieties of the cod, haddock, whiting, and the flat fish.

Almost every soft part of fishes is nutritious, and occasionally eaten. The great bulk of the animal consists of the muscles of voluntary motion, covering the spine and its appendages; but of some fishes, as turbot, ling, &c. the pulpy gelatinous skin is esteemed. Cod-sounds are the swimming bladders of the large cod, and they are preserved separately, and transmitted to the capital for the gratification of our epicures. In the fresh fish, the tongue, palate, and lips, although too soft for most people, are preferred by some. The roe of most fishes is eaten, and that of some constitutes a principal article of national food. Caviare is the preserved roe of the sturgeon. The melt or soft roe of the herring is eaten by many. The liver of the burbot is very large, and is much esteemed. The enormous *vas deferens* of the male cod fried is one of the best garnishes for that fish; and some of the smaller and more delicate fishes are eaten whole, with the exception of the head.

So far as we have knowledge of the effect of sex upon the nutritive qualities of fish, the male or melter is much preferred, as in the herring and salmon. In spring the male only of the lump-fish or cock-padle, Cyclopterus lumpus, is eaten.[2] Later in the year the female is nearly of equal quality.

Castration.

The castration and spaying of fish was at one period practised, but only to a very limited extent, and is now entirely laid aside. It was first performed by Mr Tull of Edmonton, who seems to have been a fishmonger. The earliest notice of his discovery is in the *History of the Royal Academy of Sciences of Paris for* 1742, in the extract from a letter to M. Geoffroy, from Sir Hans Sloane, in which he states that he had seen the operation performed on two small carps. A more detailed account of an improved process was afterwards published in the *Philosophical Trans-*

---

[1] Levit. ch. xi. 9, 12.

[2] Neill, *Wernerian Transactions*, vol. i. p. 548.

actions for 1754. Mr Tull's object at first was to prevent the excessive increase of fish in some of his ponds, where the numbers did not permit any of them to grow to an advantageous size; but from castration the increase was not only prevented, but the castrated fish grew much larger than their usual size, were more fat, and, what was no trifling consideration, were always in season. The operation was performed by making a longitudinal incision from between the two fore-fins almost to the anus of the fish, laying aside the intestines, first on one side, and then on the other, and dividing transversely the oviduct or vas deferens. The wound in the integuments was then stitched up, and, without further attention, few fish died of the operation. The operation was most easily performed in May, when the ovaries and spermatic vessels are full. In France Baron de la Tour operated so successfully that out of two hundred carps he did not lose four. It was also tried in Germany, and it was observed that those fish castrated in spring were in autumn still smaller than the others; but that in the following spring they were large and fat, but, some people thought, not so well tasted.[1]

Age of fish.

In regard to the age of fish as affecting their fitness for food, we are inclined to think that the adage "better small fish than none," implying that the larger they are the better, is not always correct; for although a well-grown and well-nourished individual is always finer than one not in so good condition, and although some fishes, naturally soft, may become firmer as they grow older, yet many fishes are certainly more delicate when of a smaller size, probably from being younger. Cod is generally preferred large, but we have seen large cod exceedingly coarse. The haddock is certainly better when it does not exceed a middling size; and the whole skate tribe are apt to get coarse and strong as they get large. Ausonius says the bream is the only animal which improves by old age:

> Tu melior pejore ævo, tibi contigit uni,
> Spirantum ex numero, non inlaudata senectus.

The flavour of fish is very much influenced by the nature of their food, independently of their apparent condition; and hence there is the greatest difference of the fish on different coasts, or in different rivers and lakes. In general, sea-fish are best where the water is deep, and strong or salt, and where the shore is bold and rocky. Hence the cod and ling caught near the shores, estuaries, and bays, are greatly inferior in quality to fish caught off headlands, in strong currents and deep water. Of the river fish, those which are found in clear, rapid streams, with a rocky or gravelly bottom, in a mountainous country, are indeed less fat, but better tasted; and hence the salmon of the Elbe and Rhine are more valued than those of the other continental rivers. The Thames salmon, however, is preferred in the London market to all other, and some epicures pretend to be able to distinguish by the taste when it comes from a favourite reach of the river. Certain, however, it is, that fish caught in slow-running waters, with a muddy bottom, such as occur in flat countries with a rich soil, though generally larger and fatter, are very inferior in the more essential points of flavour and firmness. Also the fish of large deep lakes, with a gravelly bottom, is much preferable to that of small, shallow, and muddy ponds or tanks. The bad qualities of fish in stagnant waters, into which the filth of cities was emptied, did not escape the notice of Galen. Fresh-water fish bred in muddy bottoms or foul water are sometimes freed from the unpleasant earthy taste by keeping them for some time in ponds of clear water with a gravelly bottom.

Season.

The season of the year has the most marked effect upon the quality of fish, as connected with their spawning. In general, fish of every kind are best some time before they begin to spawn, and are unfit for food some time after they have spawned. This, however, is not sufficient to prevent those who have an easy opportunity, from catching and eating fish in this state; and the legislature has found it necessary to fix the periods during which salmon fishing is legal. When the salmon is in the sea, and about to enter the rivers for the purpose of spawning, it is infested with a parasitical insect, which adheres to every part of the body, and dies and drops off after the fish has been for a short time in fresh water. In this state it is in the highest perfection, the flesh is firm, red, and delicious, the form elegant, and the colours beautiful. On first entering the river, the silvery colour of the sides is very slightly marked with spots; but when it has remained long in fresh water this colour decays, and the spots become much larger, darker coloured, and more obvious. At the time of spawning, the sides of the fish get of a very red colour, and when the spawning is over the white colour entirely disappears, the belly becomes livid, and the sides are streaked all over with a sooty or black colour; and in this state the salmon are termed in the acts of parliament red and black fish. The rays of their fins are all at this time jagged or torn, a great part of their scales rubbed off, and their gills infested with parasitical worms. In Ireland, where great freedom is used in destroying salmon during and after spawning season, the eating of the fish at that time has been often, and in many places, found to be productive of much disease and mortality; and the same is probably sometimes the case in Scotland, although not so much observed as to be generally known; but a very marked instance is mentioned by Dr Walker.[2]

Other fish are probably unwholesome after spawning, but they are seldom caught in that state. Young fish, not come to the age of spawning, are in season all the year.

In regard to their *habitat*, or the situation where they live, fishes may be divided into three families: 1*st*, Those which live entirely in salt water, as the cod and herring; 2*d*, those which live entirely in fresh water, as various species of the cyprinus; and, 3*d*, those which live alternately in salt and fresh water, as the salmon and sturgeon. The comparative esculent qualities of each depend upon a great variety of circumstances; but of the last class it may be remarked, that as they enter the rivers for the purpose of spawning, they are in greatest perfection when they are proceeding up the rivers, and are quite out of season when returning to the sea.

Fish seldom undergo any preparation for killing, nor is there any attention paid to the mode of depriving them of life. Most commonly they are killed as soon as caught, and frequently by merely taking them out of the water. Sometimes, when large, the fishermen strike them upon the head, or tear asunder the branchial vessels. The Dutch carry all their fresh fish alive to market, and when any die previous to being sold, they are exposed in a different manner, and at an inferior price. This practice no doubt insures fresh fish, but if certainly fresh, they will be in greater perfection if killed immediately when caught, than preserved alive for any time in an unnatural situation.

Crimp

To improve the quality of fish, they are sometimes subjected to the process called crimping. It has been exa-

---

[2] *Prize Essays and Transactions of the Highland Society of Scotland*, vol. ii. Edin. 1803. *Essays on the Natural History of Salmon*, by the Reverend Dr Walker, Professor of Nat. Hist. Univers. of Edin. A. Drummond, Esq. and Messrs Mackenzie and Morrison.

Selection of Fish.

mined by Mr Carlisle, to whom we are indebted for the following facts: "Whenever the rigid contractions of death have not taken place, this process may be practised with success. The sea-fish destined for crimping are usually struck on the head when caught, which it is said protracts the term of this capability, and the muscles which retain this property longest are those about the head. Many transverse sections of the muscles being made, and the fish immersed in cold water, the contractions called crimping take place in about five minutes; but if the mass be large, it often requires thirty minutes to complete the process." The crimping of fresh-water fishes is said to require hard water, and the London fishmongers usually employ it. Mr Carlisle found that, by being crimped, the muscles subjected to the process have both their absolute weight and their specific gravity increased; so that it appears that water is absorbed, and condensation takes place.[1] It was also observed that the effect was greater in proportion to the vivaciousness of the fish. From these observations it appears that the object of crimping is first to retard the natural stiffening of the muscles, and then, by the sudden application of cold water, to excite it in the greatest possible degree, by which means it both acquires the desired firmness, and keeps longer. We may also here observe, that rigidity is a certain mark that the fish is perfectly fresh, and has not begun to spoil.

Mollusci.

The *Mollusci* do not furnish a very extensive source of human food, and they are not without danger. Of those without shells, only the *sepiæ* and some *ascideæ* are eaten, but not generally. The limpet, *Patella vulgata*, the periwinkle, *Turbo littoreus*, and welk, *Murex antiquus*, are eaten boiled by the common people in this country; and the *Helix pomatia* is reared and fattened with great care in some cantons of Switzerland, as an article of luxury, and exported pickled. Many other snails are eaten by the poor in various districts, and we do not know that any is absolutely hurtful. The bivalves, in like manner, are generally wholesome, and some of them have long been among the *deliciæ gulosorum*. The Romans sent to Britain for oysters, and the British epicures delight in the *Pholas dactylus* of the Italian shores.

The crustaceous shell-fish of sufficient size are very generally esculent, and some of them are greatly esteemed, and others abundant. These chiefly belong to the family of *Cancer*, and comprehend both short-tailed and long-tailed species; the velvet crab, one of the most esteemed in France; the *C. mœnas*, eaten by the poor in London; *C. pagurus*, the black-toed crab; *C. ruricola*, the land crab of our Transatlantic islands; *C. gammarus*, the lobster; *C. astacus*, the craw-fish; *C. crangon*, the shrimp; and *C. squilla*, the prawn; besides others not known in this country.

Few insects are used in food. The locust is, however, consumed in great quantities, both fresh and salted, so as to afford some compensation for the ravages it commits. The Moors in West Barbary esteem as delicious, honeycomb with the young bees in it; but Mr Jones says that they seemed insipid to his palate, and sometimes gave him the heartburn.

Vegetables.

Although the vegetable kingdom furnishes the human race, even those who eat flesh most freely, with the greater part of their food, yet there are many more exceptions to the fitness for human food in the vegetable than in the animal kingdom, both from mere indigestibility or defect of nutritious qualities, and from being directly deleterious and hurtful. The selection of vegetable food, when we depart from that which is familiar and known, is therefore more difficult, and subject to uncertainty. There is, however, a certain analogy between the action on the animal economy among vegetables which resemble each other in external form, or in their botanical characters. The arrangement, therefore, of vegetables into natural groups or families, is calculated to assist us in judging of the uses, medicinal or esculent, of untried vegetables.[2]

All parts of vegetables are used as food; roots, stalks, or shoots; leaves, flowers, fruits, seeds, and the whole plant. The seeds of the *Cerealia*, the *Gramineæ* of modern botanists, furnish the most important part of our food in almost every climate. Their mucilaginous shoots also support that class of animals hence called graminivorous, whose flesh is most generally eaten; and the abundance of different species in all varieties of climate, and the absolute identity of their nature, is the cause, as De Candolle well observes, that these animals may be transported and naturalized from one end of the world to the other.

PRESERVATION.

As the supply of food is always subject to irregularities, the preservation of the excess obtained at one time to meet the deficiency of another would soon engage the attention of mankind. At first this method would be simple and natural, and derived from a very limited observation; but in the progress of society the wants and occupations of mankind would lead them to invent means by which the more perishable alimentary substances of one season might be reserved for consumption at another, or the superfluous productions of distant countries might be transported to others where they are more needed. The principles of this most important art have been nowhere better explained than in the 45th number of the *Edinburgh Review*, by an eminent vegetable physiologist.

In general, organic substances, as soon as they are deprived of life, begin to undergo certain chemical changes, more or less rapidly, and of different kinds, according to their nature. Although the modes of change, especially in the first stages, are almost as numerous as the substances themselves, yet ultimately they terminate in one or more of the principal kinds of fermentation described by chemists. To each of these, besides the presence of an organic substance capable of undergoing it, several conditions are requisite, of which the principal are a certain temperature, a certain degree of moisture, and the access of air; and it is by obviating or modifying these conditions that we are enabled to prevent or regulate the natural fermentation. The kind of fermentation which substances undergo depends upon their composition, and it may be generally remarked, that those which do not contain a considerable proportion of azote are incapable of the putrefactive fermentation, but pass through the vinous, acetous, and destructive, successively. On the other hand, those which contain a large proportion of azote are capable only of the putrefactive and destructive; but there are many substances containing a small proportion of azote, in which both kinds of fermentation are combined.

Preservation of vegetables.

A great proportion of vegetables are used in a recent state, and, in this case, the sooner after they are gathered the better. Vegetables, in general, should be kept apart; for, if laid in contact, in a very short time they impart their peculiar flavours to each other. Leeks or celery will

---

[1] *The Croonian Lectures on Muscular Motion*, by Anthony Carlisle, Esq. F. R. S. *Philosophical Transactions for* 1805, 4to, London, 1805, p. 23.

[2] *Essai sur les Propriétés Médicales des Plantes, comparées avec leurs formes extérieures et leur classification naturelle.* Par M. A. P. De Candolle, 8vo, Paris, 1816.

Preservation of Food.

quickly spoil a whole basketful of cauliflower or the finer vegetables. Another general rule is, that they should not be kept in water, nor even washed or refreshed by sprinkling them with water, till they are to be used, as the flavour is thereby greatly injured; but if, by having been cut or gathered some time, they have become flaccid, it is absolutely necessary to restore their crispness before cooking them, otherwise they will be tough and unpleasant. This is to be done when the size of the vegetable admits of it, as cauliflower, salad, celery, and the like, by cutting off a piece of the stalk and setting the fresh surface, thus exposed, in water, which will be absorbed; in other cases the whole vegetable must be immersed in water.

Most vegetable substances being more or less succulent, their full proportion of fluids is necessary for their retaining that state of crispness or plumpness which they have when growing. On being cut or gathered, the exhalation from their surfaces continues, while, from the open vessels of the cut surface, there is often great exudation or evaporation, and thus their natural moisture is diminished, and the tender leaves become flaccid, and the thicker masses or roots lose their plumpness. This is not only less pleasant to the eye, but is a real injury to the nutritious powers of the vegetable; for in this flaccid and shrivelled state its fibres are less easily divided in chewing, and the water which exists in vegetable substances, in the form of their respective natural juices, is directly nutritious. The first care in the preservation of succulent vegetables, therefore, is to prevent them from losing their natural moisture. In regard to the tender succulent vegetables this is not altogether possible, because there is a constant exhalation from their surface, while the supply of moisture is cut off. The principle of preserving them, then, is to retard and diminish the exhalation. This is most effectually done by protecting them from the action of the sun's rays, from the air, and from heat. Even growing vegetables become flaccid in a hot sun, because the exhalation is then greater than the supply; and exposure to the sun is absolutely ruinous to all the more delicate vegetables. The operation of heat and air is slower, but similar. Succulent vegetables should therefore be kept in a cool, shady, and damp place. They should also be kept in a heap, and not spread out, which greatly influences their shrivelling. But when accumulated in too large heaps for any length of time, they are injured in another way, by their heating, as it is called, which is the commencement, in them, of a chemical change, or fermentation, which altogether alters their nature. In many cases the chief business is to prevent evaporation. Potatoes, turnips, carrots, and similar roots, intended to be stored up, should never be cleaned from the earth adhering to them, because the little fibres by which it is retained are thus wounded, and the evaporating surface is increased. They should also be wounded as little as possible, and the tops of turnips and carrots should be cut off close to, but above, the root. The next thing to be attended to is to protect them from the action of the air and of frost. This is done by laying them in heaps, burying them in sand or in earth, immersing them in water, or covering them with straw or mats. The action of frost is most destructive, as, if it be considerable, the life of the vegetable is destroyed, and it speedily rots. A less degree of frost induces a singular but hurtful change upon the potato, by converting part of its starch, or mucilage, into sugar. The germination of seeds also converts their starch into sugar, as is exemplified in the malting of barley. But, even after this change has been induced, if the substance be thoroughly dried in a kiln or otherwise, it will still remain a long time without decay.

Fruits.

The maturation of fruits, although not thoroughly examined, seems to be a change of the same kind, that is, sugar is formed at the expense of the other principle of the unripe fruit. The maturation of fruits is intimately connected with a certain species of decay, as exemplified in the firmer fruits. The rotten parts of many pears is remarkably sweet, and the saccharine matter does not begin to be formed in the medlar until its decomposition be far advanced. In other instances, as in the apple, the decayed part is intensely bitter; and the softer juicy fruits grow mouldy and offensive. The art of preserving fruits consists in being able to prevent and retard these changes. A certain proportion of moisture seems to be necessary for their decay; and hence, by careful exsiccation, grapes are converted into raisins, plums into prunes, and figs are dried. But by carefully excluding them from the air, they may even be preserved without dissipating their natural moisture. Thus currants, cherries, and damsons, gathered perfectly dry and sound, may be put into bottles, closed with cork and rosin, and buried in a trench, with the cork downwards. Fine bunches of grapes may also be preserved in bags, by closing the cut end of the stalk with wax, which prevents the escape of moisture; or they may be packed in very dry bran or sand. Some may even be preserved by being kept immersed in water. This is constantly practised in regard to the cranberry, and sometimes succeeds with apples.

The preservation of fruit is in many countries an object of much importance. In some, the great object is to preserve the fruit in as natural a state as possible. This is particularly the case in regard to winter apples, and pears, and grapes. The time for gathering fruits depends upon their exposure, and the manner of gathering them influences their keeping. After having prepared the fruit-room, a fine day is to be chosen, and, if possible, after two or three preceding days of dry weather, and about two in the afternoon, the fruit is to be gathered, and deposited in baskets of a moderate size, taking care that none of it receive any bruise or blemish, for the injured part soon rots and spoils the sound fruit in contact with it. As the summer fruits ripen more quickly after they are pulled, only a few days consumption should be gathered at once, by which means we can enjoy them for a greater length of time. Autumn apples and pears should be gathered eight days before they are ripe; and, indeed, some kinds never become fit for eating on the tree. If they have been necessarily gathered in wet weather, or early in the morning, they should be exposed a day to the sun to dry, and they should on no account be wiped, which rubs off the bloom as it is called, which, when allowed to dry on some fruits, constitutes a natural varnish, closing up the pores, and preventing the evaporation of the juices. They should not be laid in heaps, which causes them to sweat, and undergo a slight fermentation; for fruit thus treated, if it does not spoil, gets dry and mealy; and hence, in this country, the ordinary apples imported from England and the Continent are inferior to our own. The principal requisites for a good fruit-room are great dryness, and equality of temperature, and the power of excluding light. Some curious persons preserve fine pears by passing a thread through the stalk, of which they seal up the end with a drop of sealing-wax, enclose each separately in a cone of paper, and hang them up by the thread brought through the apex. Experience has also proved that grapes keep better when hanging than when laid upon a table. The cut end should be closed with wax, which prevents exhalation. Some hang them by the stalk, others by the point of the bunch, as the grapes are thus less pressed against each other; but it is in both cases necessary to visit them from time to time, and cut off, with a pair of scissors, every berry that is mouldy or spoiled.

More artificial modes of preserving grapes in a succulent state are sometimes used, and become necessary for their transportation to distant countries. They are often packed with bran and saw-dust; and Apicius says they may be preserved in barley. The same classical gourmand was well acquainted with the use of water in preserving the grapes in their natural state. "Take grapes from the vine without wounding them. Boil rain water down to a third, and put it into a vessel, into which you also put the grapes. Close the vessel with pitch and gypsum, and place it in a cool situation, to which the sun has not access, and when you please you will have green grapes. The water may be given to sick persons as hydromel." The boiling of the water so long is unnecessary, as a much shorter time would be sufficient to expel the air, which is probably the manner in which it has some effect. The water will acquire a slight acidity from the grapes; and hence it was given, sweetened with honey, as a pleasant drink to the sick.

Animal substances in general, when deprived of life, have a natural tendency to undergo the putrefactive fermentation. Before this is established they pass through a series of successive changes, which are intimately connected with our subject. After death the bodies of animals cool more or less rapidly, according to the temperature and conducting power of the air, or other substances with which they are in contact. In fact they do not differ in this respect from an equal mass of any other matter, heated artificially to the same temperature, and having the same conducting power. As this, however, is very weak, the bodies of animals cool very slowly after death.

For some time after death the muscular parts of animals continue to suffer contraction, followed by relaxation, when stimulated, as by the point of a needle, or the application of galvanism. But this irritability, or organic contractility as it is termed by some modern physiologists, gradually disappears in the different organs, and commonly in the muscles of the trunk before those of the limbs. It is also observed, that, in the different classes of animals, the duration of the irritability is inversely as the energy of muscular action which they exhibit during life. It is strongest and most durable in animals which are suddenly killed when in high health, and is weak and evanescent in those which die of lingering diseases, or from fatigue.

After the irritability has entirely ceased, the muscles begin to become rigid, first those of the trunk, and then those of the limbs. Its duration is inversely as the time of its commencement; and it is longest of beginning, but is greatest and lasts longest, in those animals which are suddenly killed when in high health. It appears very quickly, and lasts a short time only, in animals which die of exhaustion or from fatigue. In whatever attitude the limbs are placed at its commencement, they continue; and hence butchers take care to dress properly the carcasses of animals while yet supple. For after rigidity has commenced, if the position of the limb be forcibly changed, it is destroyed, and the joint becomes permanently supple. Also muscles which are frozen when rigid, are extremely supple as soon as they are thawed. Rigidity is perhaps never developed in animals frozen to death.[1]

While this rigidity continues, the flesh of animals is hard and stringy, and, so far as the palate is concerned, not yet fit for the table, although fully nutritious, and in perfection for making soup. After the rigidity has totally ceased, animal flesh is not long of experiencing the commencement of those chemical changes which terminate in putrefaction; and it is of the utmost importance, in domestic economy, to take care that all large joints be in this intermediate state when they are cooked; for no skill in the culinary art will compensate for negligence in this point, as every one must have often experienced to his great disappointment. Meat in which we are able to detect the slightest trace of putrescency has reached its greatest degree of tenderness, and should be used without delay; but before this period, which in some kinds of meat is offensive, the degree of inteneration may be known by its yielding readily to the pressure of the finger, and by its opposing little resistance to an attempt to bend the joint. Poultry also thus part readily with their feathers, and it would be advisable to leave a few when the bird is plucked, in order to assist in determining their state. "No man who understands good living will say, on such a day will I eat that turkey; but let him hang it up by four of the large tail feathers, and when, on paying his morning visit to the larder, he finds it lying upon a cloth prepared to receive it when it falls, that day let it be cooked." But as we cannot always choose our time for eating the joints in our larder, we must, in providing them for a particular day, estimate that they will then be in a proper state, or, if necessary, endeavour to hasten or retard it. By experience we acquire some knowledge of the length of time for which the different kinds of meat should be kept, although it is subject to great variations, depending upon the temperature, moisture, and ventilation of the place where it is kept, upon the kind of meat, the age of the animal, and upon peculiarities in the individual not understood.

The chief means of preventing the fermentation of organic substances are, reduction of temperature, desiccation, exclusion of air, and the action of certain substances called antiseptic. Although most commonly employed in combination with each other, we shall briefly explain the principles upon which they act singly, and then notice their practical application in reference to the animal and vegetable kingdoms.

A moderate reduction of temperature acts by retarding vital and chemical action, and a reduction, capable of freezing the juices and fluids of organized bodies, by destroying vitality, and converting the water present into ice, and thus removing a condition essential to chemical action. Many vegetable, and some animal substances, such as eggs, possess what may be called latent life, and so long as this continues they resist fermentation. A very low temperature puts an end to it, while a high temperature calls it into action, after which it cannot be suspended without destroying it altogether, and thus it is longest preserved in a temperature just a little higher than the former. An egg which has been frozen is killed, and rots soon after being thawed. On the other hand, by incubation, or an equal degree of heat, the life of the chick becomes active, and cannot again be checked with impunity; while, at a moderately low temperature, the latent life of an egg continues a great length of time, ready to be excited into action when placed in favourable circumstances, and resisting the natural tendency to chemical change. The same observation nearly applies to vegetables. Succulent roots, for example, can be long preserved in a moderately low temperature; but if it be raised they begin to shoot, or if it be reduced too much they die, and soon rot.

On dead organic substances a reduced temperature acts by retarding or preventing chemical change.

The preservative effects of cold are of the utmost importance to the northern nations, by enabling them to store up a sufficient stock of all manner of provisions for their winter consumption, and to receive supplies from a great distance. It is thus that veal frozen at Archangel is brought to Petersburg, and the markets of Moscow present immense stocks of hogs, sheep, and fish. The same advantage is

Preservation of Food.

taken of the cold in Canada, and all other countries where the frost is sufficiently steady.

Substances, so long as they are hard frozen, probably undergo no chemical change, of which the most striking proof was afforded by the body of an animal, probably antediluvian, being found imbedded in a mass of ice at the mouth of the Lena; but in the act of freezing, or of the subsequent thawing, some alteration is produced, which affects the nature of the substance. This may be either merely mechanical, from the particles of ice, during their formation, tearing asunder and separating the fibres; or chemical, by destroying the intimate union of the constituents of the fluids, as in wine injured by having been frozen; or by causing new combinations, of which we have an example in the sweetness acquired by the potato.

Captain Scoresby, contrary to popular belief, states that "the most surprising action of the frost on fresh provision is in preserving it a long time from putrefaction, even after it is thawed and returns into a warm climate. I have," says he, "eaten unsalted mutton and beef nearly five months old, which has been constantly exposed to a temperature above the freezing point for four or five weeks in the outset, and occasionally assailed by the septical influences of rain, fog, heat, and electricity, and yet it has proved perfectly sweet. It may be remarked that unsalted meat that has been preserved four or five months in a cold climate, and then brought back to the British coasts during the warmth of summer, must be consumed very speedily after it is cut into, or it will fail in a day or two. It will seldom, indeed, keep sweet after being cooked above twenty or thirty hours."

In freezing animal substances for the purpose of preserving them, no other precaution is necessary than exposing them to a sufficient degree of cold. "Animal substances," says Captain Scoresby, "requisite as food, of all descriptions (fish excepted), may be taken to Greenland and there preserved any length of time, without being smoked, dried, or salted. No preparation of any kind is necessary for their preservation, nor is any other precaution requisite, excepting suspending them in the air when taken on shipboard, shielding them a little from the sun and wet, and immersing them occasionally in sea-water, or throwing sea-water over them after heavy rains, which will effectually prevent putrescency on the outward passage, and in Greenland the cold becomes a sufficient preservation, by freezing them as hard as blocks of wood." "The moisture is well preserved by freezing, a little from the surface only evaporating, so that if cooked when three, four, or five months old, meat will frequently appear as profuse of gravy as if it had been but recently killed." Captain Scoresby has not informed us why fish cannot be taken to Greenland in a frozen state, though this is a mode of preservation much used in Russia and Germany, and even in our own country.

Some attention is necessary for thawing provisions which have been frozen. "When used, the beef cannot be divided but by an axe or a saw; the latter instrument is generally preferred. It is then put into cold water, from which it derives heat by the formation of ice around it, and soon thaws; but if put into hot water, much of the gravy is extracted, and the meat is injured without being thawed more readily. If an attempt be made to cook it before it is thawed, it may be burnt on the outside, while the centre remains raw, or actually in a frozen state." These observations, which we have transcribed from Captain Scoresby,[1] an excellent observer, agree with the directions of earlier writers. Thus Krünitz says, "when fish taken under the ice are frozen, lay them in cold water, which thus draws the ice out of the fish, so that it can be scraped off their scales. They taste much better afterwards than when they are allowed to thaw in a warm room."[2] We do not know whether it be ignorance or inattention to this direction on the part of the London fishmongers which causes the salmon sent from Scotland in ice to be little esteemed.

Preservation of Food.

The second general method of preventing fermentation is desiccation, or the removal of that degree of moisture which is an essential condition to this kind of chemical action. Desiccation takes place in consequence of the air absorbing the moisture of bodies exposed to its action. It is therefore promoted by the size of surface exposed, by the dry state of the atmosphere, increased temperature, and by the constant change of the air in contact with the body to be dried, or, in other words, by exposing it to a free current of air. This mode of checking fermentation is assisted by dividing or cutting the bodies to be dried, especially across the grain, which acts not only by increasing the surface, but perhaps still more by dividing the vessels containing the moisture or fluids, and thus allowing them to be freely acted upon by the air, to which the skin or epidermis, when entire, frequently exposes a very great obstacle. In pharmacy, where exsiccation is often necessary, this is well understood, and expressed in the collegiate directions for drying squills, and other succulent roots. In domestic economy it is also practised in drying artichoke bottoms, and guarded against when vegetables are required to be kept succulent, which are or ought to be trimmed or wounded as little as possible till they are to be used. Animal substances also dry much more slowly so long as the surface is entire; and hence some country butchers skin veal joint by joint only, as it is required. The influence of extent of surface is a matter of constant observation. A little water, which would require days to evaporate out of a wine glass, disappears in a few minutes when spread over a China plate. Also solid substances dry more quickly in proportion to the smallness of their size, as the surface exposed is proportionably greater. But none of the agents in accelerating exsiccation has so great an influence as the dry state of the air by which it is effected.

Mr Hearne[3] gives an account of the manner in which the Indians of North America preserve, by means of mere exsiccation, the flesh of musk oxen, deer, or any other animal. To prepare meat in this manner, no farther operation is required than cutting the lean parts of the animal into thin slices, and drying it in the sun, or by exposing it to the heat of a fire, when it is reduced to powder by beating it between two stones. Meat prepared in this way is very portable, and always ready for use, and it is very substantial; for Mr Hearne found that he could always travel longer without victuals after making a meal of it, than after any other kind of food. The northern Indians dry their meat by the heat of a very slow fire, or by fastening it to the tops of the women's bundles, and allowing it to dry by the sun and wind as they walk along. But the southern Indians expose it to the heat of a very large fire, which, in Mr Hearne's opinion, exhausts its juices, renders it as hard as horn, and gives it a bitter taste, whereas the other is soft and mellow in the mouth, and entirely free from smoke. Fish is also dried by them in the sun, and pounded for the sake of carriage.

The third general means of preventing fermentation is the total exclusion of atmospheric air, or rather of oxygen.

---

[2] *Encyclop.* vol. x. p. 586.

[3] *Journey to the Northern Ocean.*

The truth of this is not so obvious to common observation as that of the others; for, on the contrary, we every day see substances spoiled by being apparently excluded from the air, but in reality by being shut up in confined air; and we are taught to consider free ventilation as a powerful means of preservation. The manner in which the latter acts we have shown to be by removing moisture, especially when contaminated by the exhalation of the perishable substance. The *rationale* of the former is more obscure, but has been ingeniously attempted by Gay-Lussac, and the *Edinburgh Review* (No. xlv.), in order to explain the processes of M. Appert. Gay-Lussac found that neither fresh vegetable juices nor animal matter fermented so long as oxygen gas was perfectly excluded; and that the fermentation, in both cases, commenced as soon as any portion of oxygen was admitted. When oxygen gas is confined in contact with a fermentable substance, it is changed into an equal bulk of carbonic acid gas, and all farther action ceases. Methods of preserving fermentable substances, illustrative of this principle, have long been practised imperfectly by housewives. Nothing can be simpler than Mr Raffald's receipt for preserving green peas, cranberries, currants, &c. "Put them into dry clean bottles, cork them close, and tie them with a bladder; keep them in a cool dry place." A variation of this process was to fill the bottles previously with sulphurous acid vapour, by holding in them for some time a lighted sulphur match. One effect of this is to remove all uncombined oxygen. Other methods of excluding air were also employed, as filling up the interstices with water or melted suet. The success of this process was greatly promoted by subjecting the substances to the action of a certain degree of heat, after being put into the bottles or jars in which they were to be preserved; and then we are desired "to set them in a copper of hot water till they are hot quite through," or to "put them in an oven when the bread is drawn, and let them stand till shrunk a quarter part."

In these cases the heat seems to act by coagulating and rendering insoluble and inactive a kind of gluten, which seems to be a principal agent in beginning fermentation. In general, in the old processes, we were directed not to cork or tie up the vessels until they were quite cool, by which it now appears a very great advantage was lost. But Mr Saddington obtained, in 1817, a premium from the Society of Arts for a method of preserving fruit without sugar, for house or sea stores; the chief peculiarity of which consisted in filling the bottles, as soon as they are taken out of the bath, with boiling water to within an inch of the cork, and immediately corking them very tight and laying them on their sides, that the cork may swell and effectually exclude the air. Animal substances have also long been occasionally preserved by the mere exclusion of air. The most familiar example is the buttering of eggs, which has the effect of closing the pores in the shell by which the communication of the embryo with the external air takes place. It is best performed by rubbing over the shell with butter while it is still warm after being laid; and an egg in this way retains the curdy milk, and possesses all the properties of a new-laid egg for a great length of time; but at whatever period after being laid the egg is buttered over, its progress to decay seems to be arrested. The same effect is produced, though not so perfectly, by immersing eggs in water. From an experiment of Reaumur's, it appears that the cutting off the access of air to the embryo in the egg does not kill it or prevent it from being hatched, but, on the contrary, preserves it alive for a much greater time than if it had not been treated in this manner. He covered over eggs with spirit varnish, and he found them capable of producing chickens after two years, when the varnish was carefully removed.

Although, however, the preservation of alimentary matters by the total exclusion of air, assisted by subjecting them to a certain degree of heat, has long been practised in some degree, we are certainly indebted to M. Appert,[1] who first published in 1810, for the regular and scientific application of these principles upon a large scale. From extensive experience and long perseverance he became convinced,

"1*st*, That fire has the peculiar property, not only of changing the combination of the constituent parts of vegetable and animal productions, but also of retarding, for many years at least, if not of destroying, the natural tendency of those same productions to decomposition.

"2*dly*, That the application of fire in a manner variously adapted to various substances, after having, with the utmost care, and as completely as possible, deprived them of all contact with the air, effects a perfect preservation of those same productions, with all their natural qualities."

Upon these principles he invented many processes adapted to the different natures of the substances to be preserved; but the fundamental conditions consist, 1*st*, In enclosing in bottles the substances to be preserved. 2*dly*, In corking the bottles with the utmost care; for it is chiefly on the corking that the success of the process depends. 3*dly*, In submitting these enclosed cases to the action of boiling water in a water-bath (*Balneum Mariæ*), for a greater or less length of time, according to their nature, and in the manner pointed out with respect to each several kind of substance. 4*thly*, In withdrawing the bottles from the water-bath at the period described.

M. Appert employed at first bottles made of glass, which it was difficult to close exactly, especially when their mouths were large; but he now uses cylinders of tin plate, which are soldered up after they are filled. This is especially an improvement for animal substances, which require much more attention than vegetables. Tin cases or canisters seem to have been first used in London by Messrs Donkin and Gamble, by whom a very ingenious method of testing the provisions put up by them was also invented as early as 1813.[2] The substances to be preserved are first parboiled, or somewhat more. The vegetables and meat, the bones being removed, are then put into tin cylinders, which are filled up with the broth, and the lid soldered down. It now undergoes the remainder of the cooking, when a small hole is opened at the top of the cylinder, and immediately closed with solder while still hot. The whole is now allowed to cool, and from the diminution of volume in the contents, in consequence of the reduction of temperature, both ends of the cylinder are pressed inwards and become concave. The cases thus hermetically sealed are exposed in a *test-chamber*, for at least a month, to a temperature above what they are ever likely to encounter; from 90° to 110° Fahrenheit. If the process has failed, putrefaction takes place, and gas is evolved, which in process of time will bulge out both ends of the case, so as to render them convex instead of concave. But the contents of whatever cases stand this test will infallibly keep perfectly sweet and good in any climate, and for any length of time. Another advantage is, that if there be any taint about the meat when put up, it inevitably ferments, and is detected in the proving.

---

[1] *Le Livre de tous les Ménages ; ou l'art de conserver pendant plusieurs années toutes les substances animales et végétables*, 3me edit. Paris 1813.

[2] In a patent granted in 1819 to Mr Æneas Morrison of Glasgow, for preserving food upon similar principles, the corks or bungs are perforated by a tin tube, which is hermetically sealed by driving down a tin plug whilst the vessel is still quite hot and filled with steam.

All kinds of alimentary matters may be preserved in this way,—beef, mutton, veal, and poultry, boiled and roasted, soups, broths and vegetables, creams and custards. The testimonies in favour of the success of the process are of the most unexceptionable kind. The meat is put up in canisters of from four pounds to twenty pounds weight each, and the milk and soups in quart or pint bottles. The meat is charged from 1s. 8d. to 3s. a pound; roast higher than boiled, and veal dearer than mutton or beef. The milk is 24s. per dozen for quarts, 15s. for pints, and 10s. for half pints; and soups from 30s. to 60s. per dozen for quarts. The weight of the canister is deducted, and nothing is charged for canisters or bottles; and it should be observed, that the patent provisions being cooked, and without bone, render them nearly equivalent to double the weight of meat in the raw state; for, by experiment, the patentees found, that the waste in cooking, and weight of bone, are about one half. Captain Neish took a quantity to India; not one canister spoiled; and one which he brought home contained beef in the highest state of preservation after two years, and having been carried upwards of 35,000 miles in the warmest climates. The commissioners for victualling the navy also examined some nearly four years old, which had been in the Mediterranean and Quebec, and found it as sound, sweet, and fresh, as if it had been only yesterday boiled. We are also enabled to add the testimony of Captain Basil Hall, who has liberally communicated to us the result of his personal experience and observation: "I can answer for the perfect preservation of a great number of cases which were in my possession during the voyage to China. I had L.88 worth, and not one failure. At that time milk was preserved in bottles corked; but tin cases have been substituted with very great effect, as I have myself tried. It is really astonishing how excellent the milk is; and, indeed, every thing preserved in this way is good.

"You must, on examining the lists of prices, bear in mind that meat thus preserved *eats* nothing, nor *drinks*—is not apt to get the rot, or to die—does not *tumble* over board, nor get its legs broken or its flesh worn off its bones by knocking about the decks of a ship in bad weather—it takes no care in the keeping—it is always ready, may be eat cold or hot, and thus enables you to toss into a boat in a minute as many days' *cooked* provisions as you choose—it is not exposed to the vicissitudes of markets, nor is it scourged up to a monstrous price, as at St Helena, because there is no alternative. Besides these advantages, it enables one to indulge in a number of luxuries which no care or expense *could* procure."

The property of salt to preserve animal substances from putrefaction is of most essential importance to the empire in general, and to the remote grazing districts in particular. It enables the latter to dispose of their live stock, and distant navigation is wholly dependent upon it. All kinds of animal substances may be preserved by salt, but beef and pork are the only staple articles of this kind. In general, the pieces of the animal best fitted for being salted are those which contain fewest large blood-vessels, and are most solid. Some recommend all the glands to be cut out, and say, that without this precaution meat cannot be preserved; but that this is a mistake, the salt udder, and glands of the tongue, every day's experience shows.

The salting may be performed either by dry rubbing, or by immersing the meat in pickle. Cured in the former way the meat will keep longer, but it is more altered in its valuable properties; in the latter way it is more delicate and nutritious. Six pounds of salt, one pound of sugar, and four ounces of saltpetre, boiled with four gallons of water, skimmed and allowed to cool, forms a very strong pickle, which will preserve any meat completely immersed in it. To effect this, which is essential, either a heavy board, or flat stone, must be laid upon the meat. The same pickle may be used repeatedly, provided it be boiled up occasionally with additional salt to restore its strength, diminished by the combination of part of the salt with the meat, and by the dilution of the pickle by the juices of the meat extracted. By boiling, the albumen, which would cause the pickle to spoil, is coagulated, and rises in the form of scum, which must be carefully removed.

Dry salting is performed by rubbing the surface of the meat all over with salt; and it is generally believed that the process of salting is promoted if the salt be rubbed in with a heavy hand. On the contrary, it is said, that in very hot countries, for example, Jamaica, where it is so necessary that the action of the salt should take place as quickly as possible, the mode of salting a round of beef is to place it on two sticks over a tub of water, with the small end uppermost, and to cover it with a heap of salt, which penetrates through the veins and arteries, and among the fibres, in the state of a saturated solution. However this may be, it is almost certain that very little salt penetrates, except through the cut surfaces, to which it should therefore be chiefly applied; and all holes, whether natural or artificial, should be particularly attended to. For each twenty-five pounds of meat, about a pound of coarse-grained salt (St Ubes' is the best) should be allowed, and the whole, previously heated, rubbed in at once. When laid in the pickling tub, a brine is soon formed by the salt dissolved in the juice of the meat which it extracts, and with this the meat should be rubbed every day, and a different side turned down. In ten or twelve days it will be sufficiently cured.

For domestic use, the meat should not be salted as soon as it comes from the market, but kept until its fibre has become short and tender, as these changes do not take place after it has been acted upon by the salt. But in the provision trade, "the expedition with which the animals are slaughtered, the meat cut up and salted, and afterwards packed, is astonishing."[1] By salting the meat while still warm, and before the fluids are coagulated, the salt penetrates immediately, by means of the vessels, through the whole substance of the meat; and hence meat is admirably cured at Tunis, even in the hottest season; so that Mr Jackson, in his *Reflections on the Trade of the Mediterranean*, recommends ships being supplied there with their provisions.

"Take half a pound of black pepper, half a pound of red or kyan pepper, and half a pound of the best saltpetre, all beat or ground very fine; mix these three well together, then mix them with about three quarts of very fine salt: this mixture is sufficient for eight hundredweight of beef. As the pieces are brought from the person cutting up, first sprinkle the pieces with the spice, and introduce a little into all the thickest parts; if it cannot be done otherwise, make a small incision with a knife. The first salter, after rubbing salt and spice well into the meat, should take and mould the piece, the same as washing a shirt upon a board; this may be very easily done, and the meat being lately killed, is soft and pliable; this moulding opens the grain of the meat, which will make it imbibe the spice and salt much quicker than the common method of salting. The first salter hands his piece over to the second salter, who moulds and rubs the salt well into the meat, and, if he observes occasion, introduces the spice; when the second salter has finished his piece, he folds it up as close as possible, and hands it to the packer at the harness tubs, who must be stationed near him: the packer must be careful to pack his harness tubs as close as possible.

---

[1] Wakefield's *Ireland*, vol. i. p. 750.

"All the work must be carried on in the shade, but, where there is a strong current of air, the harness tubs in particular; this being a very material point in curing the meat in a hot climate. Meat may be cured in this manner with the greatest safety when the thermometer, in the shade, is at 110°, the extreme heat assisting the curing.

"A good sized bullock, of six or seven hundredweight, may be killed and salted within the hour.

"The person who attends with the spice near the first salter has the greatest trust imposed upon him; besides the spice, he should be well satisfied that the piece is sufficiently salted before he permits the first salter to hand the piece over to the second salter.

"All the salt should be very fine, and the packer, besides sprinkling the bottom of his harness tubs, should be careful to put plenty of salt between each tier of meat, which is very soon turned into the finest pickle. The pickle will nearly cover the meat as fast as the packer can stow it away. It is always a good sign that the meat is very safe when the packer begins to complain that his hands are aching with cold.

"By this method, there is no doubt but that the meat is perfectly cured in three hours from the time of killing the bullock. The saltpetre in a very little time strikes through the meat: however, it is always better to let it lie in the harness tubs till the following morning, when it will have an exceeding pleasant smell on opening the harness tubs; then take it out and pack it in tight barrels, with its own pickle."

Beef and pork, in a less degree, properly salted with salt alone, acquire a green colour; but if an ounce of saltpetre be added to each five pounds of salt employed, the muscular fibre acquires a fine red colour; but this improvement in appearance is more than compensated by its becoming harder and harsher to the taste; to correct which, a proportion of sugar or molasses is often added. But the red colour may be given if desired, without hardening the meat, by the addition of a little cochineal.

Meat, when salted, is either preserved immersed in pickle, in close vessels, or dried, when it gets the name of bacon, ham, or hung beef.

Meat kept immersed in pickle rather gains weight. In one experiment by Messrs Donkin and Gamble, there was a gain of three per cent., and in another of two and a half; but in the common way of salting, when the meat is not immersed in pickle, there is a loss of about one pound or one and a half in sixteen.

The drying of salt meat is effected either by hanging it in a dry and well-aired place, or by exposing it at the same time to wood smoke, which gives it a peculiar flavour, much admired in Westphalia hams and Hamburg beef, and also, perhaps, tends to preserve it, by the antiseptic action of the pyrolignic acid. When meat is to be hung, it need not be so highly salted.

Fish, in like manner, may be preserved either by dry salting or in pickle. The former method is employed to a great extent on the banks of Newfoundland and in Shetland. For information on this important subject, the article FISHERY may be consulted.

Dr Hibbert thinks that the cod-fish prepared in Shetland will always maintain its pre-eminence over the cod of other places. In Newfoundland the fish are said to be exposed, after being salted, on standing flakes, made by a slight wattle, and supported by poles, often twenty feet from the ground. But the humidity is not nearly so well extracted from the fish as when, according to the Shetland method, they are carefully laid out upon dry beaches, the stones of which have been during winter exposed to the abrading action of the ocean, and are thus cleared from animal and vegetable matter.[1]

The Dutch derive great national advantages from the preference given to the herrings caught upon our own coasts, when cured by them. They use no other than the Spanish or Portuguese salt, preserve no fish that they are not able to cure between sunrise, when the nets are drawn, and sunset, when they are again shot, and pay particular attention in giping, sorting, and packing each kind by itself. They fill up the barrels with fish of the same kind and night's catching, and are exceedingly careful of the pickle, as they use no other in filling of the barrels.[2]

Herrings and salmon are also often cured by drying them in wood smoke after being slightly salted, and are called red herrings or Yarmouth herrings, and kipper or smoked salmon.

Butter is commonly preserved by working into each pound one or two ounces of salt, until they be thoroughly incorporated. The best salt for the purpose is in large crystals, and it should be thoroughly dried and coarsely powdered. But Dr Anderson recommends for the curing of butter, a mixture of two parts of the best great salt, one of sugar, and one of saltpetre, beat into a fine powder. One ounce of this mixture is sufficient for a pound of butter. He says that butter cured in this way does not taste well till it has stood at least a fortnight after being salted; but after that period it has a rich marrowy taste, that no other butter ever acquires, and tastes so little salt, that one would imagine it would not keep; and yet Dr Anderson has seen it perfectly sound and sweet when two years old.

Butter spoils and becomes rancid, chiefly from the milk, which is not entirely expressed from it, and in consequence of the albumen, which is constantly present. These may be separated by melting the butter and keeping it over the fire until all the water be evaporated, when the albumen will also be coagulated, and sink to the bottom. To prevent all risk of producing an empyreumatic taste, the vessel containing the butter should not be exposed directly to the fire, but placed in a larger vessel filled with water, which is made to boil, forming what the chemists call a water-bath. While the butter remains fluid, it resembles a perfectly transparent oil, and on cooling it becomes opaque, and is firmer and a little paler than the butter before it was clarified. It will keep for a considerable time without salt; but if it be salted as common butter, it will continue much longer sweet in hot climates, than if it had been cured in its original state.[3]

The natives of Hindustan never use butter, but prefer what is called *ghee*, because it keeps better, and has more taste and smell. Their butter is prepared from coagulated acid milk; and in order to collect a sufficient quantity, it is often kept two or three days, by which time it is highly rancid. It is melted in an earthen pot, and boiled until all the water be evaporated. After being taken from the fire, a little coagulated acid milk and salt, or betel leaf and reddle, are added. It is kept in pots, and eaten when even a year old.[4]

Preservation of Food.

Vinegar, in itself a very destructible substance when exposed to the air, tends greatly to preserve vegetable substances when both are carefully excluded from it. In general, however, the vegetable is previously salted. After the pickles are prepared, the bottles are to be carefully corked, tied up with bladder, and sealed over with wax or rosin. For the making of pickles, the vinegar now distilled from wood, as in itself containing no principles of decay, must be preferable to common vinegar.

M. Parmentier has given a minute description of the process of making sour krout on the great scale. The heads of winter cabbages, after removing the outer leaves, are to be cut into fine shreds, by means of an instrument made on purpose, and then spread out to dry upon a cloth in the shade. A cask is to be set on end, with the head taken out. If it formerly contained vinegar or wine, so much the better, as it will promote the fermentation, and give the cabbage a more vinous taste; if not, the inside may be rubbed over with some krout barm. Caraway seeds are to be mixed with the shreds of cabbage, a good layer of salt placed at the bottom of the cask, and then cabbage shreds to be evenly packed, to the depth of six inches. A man having on strong boots, well washed and nicely clean, must now get into the cask, and tread down the shreds to half their original bulk. The same process is to be repeated, with additional layers of salt and shreds, till the whole be packed. They are then to be covered with a layer of salt, or till the barrel be filled within two inches of the top, over which the outside leaves of the cabbages are to be spread. About two pounds of salt are required for twenty cabbages.

The head of the barrel, which should have been previously well fastened together, is lastly to be put within the barrel above the leaves, and loaded with stones, to prevent the mixture from rising during the fermentation. The mass thus compressed subsides, and the cabbages give out their juice, which rises to the surface, is green, muddy, and fetid. It is to be drawn off by a spigot placed two or three inches down, and replaced by fresh brine every day, until it come off clear, which will take twelve or fifteen days, according to the temperature of the place. The essential point for keeping sour krout good, is to take care that it be always covered at least an inch with pickle. For home consumption enough may be made at one time to serve the year, and the pickle is then renewed at the beginning of spring, and at midsummer. When intended as ship provision for long voyages, the sour krout must be repacked very firmly into other casks, which are then to be filled with fresh pickle, and closed as accurately as possible. When well made and preserved, it has a very pleasant acidity, and is not only very healthy, but agrees with many persons who cannot use fresh cabbages. It is also considered to be a very excellent antiscorbutic; and Captain Cook attributed his success in preserving the health of his crew in his voyage partly to its use.

Vinegar is never used for the preservation of butcher meat, but salmon is often pickled in it, with the addition of salt and spices.

Pryolignic acid has lately been much extolled, as having a specific power in preserving animal matters. It consists of acetic acid, impregnated with an empyreumatic oil. The acid is in general very strong, and being free from the mucilage which promotes the spoiling of common vinegar, it is so far a better antiseptic; but the empyreumatic oil may also add to its powers, either by keeping away insects, to which it is very offensive, or by a direct antiseptic power not understood. Professor Jörg of Leipsic is said to have recovered tainted flesh by rubbing it with the oil separated from the acid; and there is no doubt that the smoking of beef, hams, salmon, and herrings, makes them keep longer than the mere drying, and the degree of previous salting, would lead us to expect.

Sugar has also the power of preserving vegetable substances from decay, but, on account of its expense, it is only used for fine fruits and aromatic substances. The preservation of these by means of sugar constitutes a principal part of the art of confectionary, and attention to many minutiæ is necessary for the success of each preparation. The most general principles only can be noticed here.

Vegetable substances may be either preserved in syrup or candied; or their juices may be employed in making syrups, jellies, or fruit-cakes. The art of confectionary is very difficult, and, to attain perfect success, requires attention to many particulars, which at first seem frivolous and even improper, but which have been found by experience to be essential. The clarification and boiling of the sugar to its proper degree is of primary importance, and has not perhaps been sufficiently examined by scientific men.

A weak syrup has a tendency to ferment, and quickly becomes sour if kept in a temperate degree of heat; it is therefore not calculated to prevent the natural fermentation of vegetable juices, which always increase its tendency to corrupt. Pharmaceutists have ascertained that a solution, prepared by dissolving two parts of double-refined sugar in one of water, or any watery fluid, and boiling the solution a little, forms a syrup, which neither ferments nor crystallizes; and the proportion may be considered as the basis of all syrups, and seems to be the degree of boiling syrup called smooth by the confectioners, as exemplified in their *Syrops de Capillaire, Orgeat*, and others.

Sugar is equally powerful in preserving animal substances from putrefaction. As a novelty to modern artists, we translate from their great precursor, Cælius Apicius, a method of preserving meat at any time without salt: "Let fresh meat of any kind be covered with honey; but hang up the vessel, and use it when you please. This succeeds better in winter; but will last a few days in summer. The same may be done with meat that has been cooked."

Other methods of preserving food have been tried, but rather as a matter of curiosity than utility.

The property of charcoal to restore sweetness to flesh beginning to be tainted, was first pointed out by M. Lowitz in Petersburg, in 1786,[1] who made numerous experiments upon the subject. For their success, it is necessary that the charcoal have been recently burnt, and that it be applied in a certain quantity. Too little fails in its effect, and too much affects the nature of the substance upon which it acts. By some it has been supposed to act merely mechanically, by absorbing fluid and putrescent exudations; but it is more probable that it acts chemically, by absorbing oxygen gas from the air in contact with the meat. In the fourth volume of the *Journal of Science* (p. 367), there is an account of some successful experiments, in which alternate layers of meat and charcoal were packed in canisters, previously filled with carbonic gas, and then carefully luted up and covered with bladder.

In the *Journal de Pharmacie* for September 1818, M. Raymond, professor of chemistry at Lyons, has related some experiments which he made upon the antiseptic properties of chlorine. Beef exposed to the action of this gas for a few minutes underwent no change in the course of six months, except becoming dry from the action of air and time. A Guinea pig, suffocated in the same gas, and afterwards immersed for a few minutes in water saturated with chlorine, and then exposed to the air for four months, without having its entrails removed, showed no sign of putrefaction in four months. He also found that tainted meat recovered the smell and appearance of fresh meat by being immersed in liquid chlorine.

PREPARATION.

Alimentary matters are used either in their crude or raw state, or after having undergone some kind of preparation.

Fruits and salads, although they admit of various forms of cookery, are most frequently eaten in as fresh and natural a state as possible.

Cookery is either necessary to destroy some deleterious property, or to render food more palatable and nutritious. Of the former effect the most remarkable example is furnished by various species of *arum*, which in their crude state are acrid, or even poisonous, but by being cooked become mild and wholesome. The acrimony resides in a very volatile principle, which is easily dissipated by heat. A more familiar example in this country is furnished by the onion tribe, the acrimony and flavour of which are entirely destroyed by being long subjected to the action of heat.

Numerous as the receipts are, the processes of cookery are but few. In some, the chief object is to extract the fluid or soluble parts of the substance cooked; in others, to alter the nature of the substance itself, and often to combine both purposes. Fire is a principal agent in almost all the processes of cookery, and the most economical mode of applying it has engaged the attention of many philosophers and artists.[1]

Convenience and economy are the objects proposed by all alleged improvements. The nature of the fuel is of no little importance, and is different in different countries. Pit coal has the advantage of forming a lasting fire, and producing an intense degree of heat, which renders it almost indispensable for roasting; but its smoke is very detrimental, both by the unpleasant flavour it imparts, and by the inconvenience arising from the flame, and from the soot deposited upon the vessels and in the chimney. Wood and turf evolve less smoke, but their flavour is more penetrating, and they give less heat, and are less durable. The cleanest and most generally useful fuel is charcoal of wood, or coke, neither giving out any smoke, or imparting any flavour. Charcoal is more easily kindled, but coke lasts longer, and gives out more heat. Well burnt cinders are an excellent substitute for coke, which in every family ought to be carefully preserved for the purposes of cookery.

The heat, from whatever fuel produced, is applied in various ways to the substances to be cooked, either directly or indirectly. Heat is applied directly, as radiant heat in the process of roasting, in which the effects are produced entirely by the rays of heat impinging directly upon substances placed at a short distance before it. For this purpose a clear glowing fire is necessary, and the bars of a good roasting grate should impede as little as possible the radiation of its heat. Another very direct mode of applying heat, is by placing the substance over the fire by suspending it in the stream of heated air ascending from it, or laying it directly on the burning fuel, or on bars, or a plate of iron, or other substance capable of supporting the heat. Broiling is the result of this mode of applying heat. Heat is also often applied through the intervention of fluids, chiefly of water or steam, as in boiling or stewing; or of some oily substance, as in frying. The peculiarity of baking consists in the substance being heated in a confined space, which does not permit the escape of the fumes arising from it.

To understand the theory of cookery, we must attend to the action of heat upon the various constituents of alimentary substances, as applied directly and indirectly through the medium of some fluid. In the former way, as exemplified in the processes of roasting and broiling, the chief constituents of animal substances undergo the following changes: the fibrine is corrugated, the albumen coagulated, the gelatine and osmazome rendered more soluble in water, the fat liquefied, and the water evaporated. If the heat exceed a certain degree, the surface becomes first brown, and then scorched. In consequence of these changes, the muscular fibre becomes opaque, shorter, firmer, and drier; the tendons less opaque, softer, and gluey; the fat is either melted out, or rendered semitransparent. Animal fluids become more transparent; the albumen is coagulated and separated, and they dissolve gelatine and osmazome. Lastly, and what is the most important change, and the immediate object of all cookery, the meat loses the vapid nauseous smell and taste peculiar to its raw state, and it becomes savoury and grateful. Heat applied through the intervention of boiling oil or melted fat, as in frying, produces nearly the same changes, as the heat is sufficient to evaporate the water, and to induce a degree of scorching. But when water is the medium through which heat is applied, as in boiling, stewing, and baking, the effects are somewhat different, as the heat never exceeds 212°, which is not sufficient to commence the process of browning or decomposition, and the soluble constituents are removed by being dissolved in the water, forming soup or broth; or, if the direct contact of the water be prevented, they are dissolved in the juices of the meat, and separate in the form of gravy.

It is evident, that whether the heat be applied directly or indirectly, there must be a considerable loss in the cooking of animal substances in public institutions, where the allowance of meat is generally weighed out in its raw state, and includes bones, and is served out cooked, and sometimes without bone; and it is a matter of importance to ascertain nearly their relative proportions. Much, no doubt, depends upon the piece of the meat cooked, and the degree of cookery, and the attention bestowed upon it. We have been informed by persons who salt rounds of beef to sell by retail after they are boiled, that they are able to get 19 lb. of cold boiled beef from 25 lb. raw; but the meat, it must be confessed, is always rather under-done. Messrs Donkin and Gamble boiled in steam 56 lb. of Captain's salt beef; the meat, when cold, without the bones, which amounted to 5 lb. 6 oz. weighed only 35 lb. In another experiment, 113 lb. of prime mess beef gave 9 lb. 10 oz. of bones, and 47 lb. 8 oz. meat; and in a third, 213 lb. mess beef gave 13 lb. 8 oz. bones, and 103 lb. 10 oz. meat; or, taken in the aggregate, 372 lb. of salt beef, including bones, furnish, when boiled, 186 lb. 2 oz. without bone, being about 50 per cent.; or, disregarding the bone altogether, salt meat loses, by boiling, about 44·2 per cwt. We are indebted to Professor Wallace, of the University of Edinburgh, for the detail of a very accurate and extensive experiment in a public establishment, of which the results were, that, in pieces of 10 lbs. weight, each 100 lbs. of beef lost, on an average, by boiling, 26·4; baking, 30·2; and roasting, 32·2: mutton, the leg, by boiling, 21·4; by roasting, the shoulder 31·1, the neck 32·4, the loin 35·9. Hence, generally speaking, mutton loses, by boiling, about one fifth of its original weight, and beef about one fourth; again, mutton and beef lose, by roasting, about one third of their original weight.

The loss arises in roasting from the melting out of the fat and evaporating the water, but the nutritious matters remain condensed in the cooked solid; but in boiling, the loss arises partly from fat melted out, but chiefly from gelatine and osmazome dissolved in the water in which the meat is boiled; there is therefore a real loss of nourishment unless the broth be used, when this mode of cooking becomes the most economical.

---

[1] See Rumford's *Essays*; Fournier, *sur les Substances Alimentaires*; *Repertory of Arts*; *Archives des Découvertes*.

Vegetable substances are most commonly boiled or baked; or, if apparently fried or roasted, there is always much water present, which prevents the greater action of the fire from penetrating below the surface. The universal effect of cookery upon vegetable substances, is to dissolve in the water some of their constituents, such as the mucilage and starch, and to render those that are not properly soluble, as the gluten and fibre, softer and more pulpy.

We cannot pretend to enter into the details of the various processes, nor explain the many precautions requisite to ensure success. For practical receipts we recommend *L'Art de Cuisinier*, par A. Beauvilliers; *A New System of Domestic Cookery*, by a Lady; and, lastly and chiefly, *Apicius Redivivus, or the Cook's Oracle*, in which, along with the plainest directions, there is more of the philosophy, and, if we may so speak, of the literature, of *gastronomie*, than in any work we have seen. The reader is also referred to a very curious volume by Mr Accum, on *Adulterations of Food*, and to a German work on the same interesting subject by Knoblauch. The unprecedented success of the *Almanach des Gourmands*, and of the *Manuel des Amphytrions*, shows how much may be made of the subject by a man of talents; nor do the writings of M. Grimod de la Reynière surpass in wit the entertaining articles in the *Edinburgh Review*, No. xi. and in the *Quarterly Review*, No. xlv. (Z.)

FOOSHT, an island in the Red Sea, situated, according to the observations of Mr Bruce, in lat. 13. 59. 43. N. It is described by him as about five miles in length from north to south; and it is low and sandy in the southern part, but in the north rises a black hill of inconsiderable height.

FOOT, a part of the body of certain animals, on which they stand, walk, or run. See ANATOMY.

FOOT, in the Latin and Greek poetry, a metre or measure, which is composed of a certain number of long and short syllables.

Of metrical feet, which are commonly reckoned twenty-eight, some are simple, consisting of two or three syllables, and therefore called *dissyllabic* or *trisyllabic feet;* and others are compound, consisting of four syllables, from which circumstance they are called *tetrasyllabic feet.*

The dissyllabic feet are four in number; the pyrrichius, spondeus, iambus, and trocheus. The trisyllabic feet are eight in number; the dactylus, anapæstus, tribrachys, molossus, amphibrachys, amphimacer, bacchius, and antibacchius. The tetrasyllabic are sixteen in number; the procelcusmaticus, dispondeus, choriambus, antispastus, diambus, dichoreus, ionicus a majore, ionicus a minore, epitritus primus, epitritus secundus, epitritus tertius, epitritus quartus, pæon primus, pæon secundus, pæon tertius, and pæon quartus.

FOOT is also a long measure consisting of twelve inches. Geometricians divide the foot into ten digits, and the digit again into ten lines.

FOOT Square is the same measure both in breadth and length, containing 144 square superficial inches.

Cubic or *Solid FOOT*, is the same measure in all the three dimensions of length, breadth, and depth or thickness, containing 1728 cubic inches.

FOOTE, SAMUEL, was born at Truro, in Cornwall, and descended from an ancient and respectable family. His father was member of parliament for Tiverton in Devonshire, and enjoyed the post of commissioner of the prize office; his mother was heiress of the Dinely and Goodere families. Foote was educated at Worcester College, Oxford, which owed its foundation to Sir Thomas Cookes Windford. On leaving the university he commenced student of law in the Temple; but as the dryness of this study did not suit the liveliness of his genius, he soon relinquished it. He then married a young lady of a good family and some fortune; but their tempers not agreeing, harmony did not long subsist between them. He now launched into all the fashionable follies of the age, gambling not excepted, and in a few years squandered away his whole fortune. His necessities led him to the stage, and he made his first appearance in the character of Othello. He next performed Fondlewife with much greater applause; and this, indeed, was ever afterwards one of his capital parts. He likewise attempted Lord Foppington, but afterwards gave it up as unsuitable to his talents. In 1747 he opened the little theatre in the Haymarket, taking upon himself the double character of author and performer; and he appeared in a dramatic piece of his own composition, called the *Diversions of the Morning*. The piece consisted of nothing more than the exhibition of several characters well known in real life, whose style and manner of conversation and expression the author had very happily hit off in the diction of his drama, and still more happily represented on the stage, by an exact and indeed amazing imitation, not only of the manner and tone of voice, but even of the very persons of those whom he intended to take off. This performance at first met with some opposition from the civil magistrates of Westminster, under the sanction of the act of parliament for limiting the number of playhouses, as well as from the jealousy of one of the managers of Drury Lane theatre. But the author being patronized by many of the principal nobility, and other persons of distinction, this opposition was overruled; and having altered the title of his performance, Mr Foote proceeded, without further molestation, to give *Tea in a Morning* to his friends, and represented it through a run of forty mornings to crowded and splendid audiences. In the ensuing season he produced another piece of the same kind, which he called *An Auction of Pictures*. Into this performance he introduced several new and popular characters; particularly Sir Thomas de Veil, then the acting justice of peace for Westminster, Mr Cock the celebrated auctioneer, and the equally famous Orator Henley. The *Auction* had also a very great run. His *Knights*, which was the production of the ensuing season, exhibited somewhat more of dramatic regularity. But still, although his plot and characters seemed less immediately personal, it was apparent that in the performance he kept some real persons strongly in his eye; and the town took it upon themselves to fix these where the resemblances appeared most striking. Thus Mr Foote continued from time to time to select, for the entertainment of the town, such public characters as seemed most likely to engage their attention. But his dramatic pieces, exclusively of the interlude called *Piety in Pattens*, are only to be ranked among the *petites pièces* of the theatre. In the execution they are somewhat loose, negligent, and unfinished; the plots are often irregular, and the catastrophes frequently inconclusive; but, with all these deficiencies, they contain more strength of character, more strokes of keen satire, and more touches of temporary humour, than are to be found in the writings of any other modern dramatist. Even the language spoken by his characters, incorrect as it may sometimes seem, will on a closer examination be found altogether dramatical: abounding with those natural minutiæ of expression which frequently form the very basis of character, and which render it the truest mirror of the conversation of the times to which it applies.

In the year 1766, being on a party of pleasure with the Duke of York, Lord Mexborough, and Sir Francis Delaval, Mr Foote had the misfortune to break his leg by a fall from his horse, in consequence of which he was compelled to undergo an amputation. This accident so sensibly affected the duke, that he made a point of obtaining for Mr Foote a patent for life, by which he was allowed to perform, at the little theatre in the Haymarket, from the 15th of May to the 15th of September every year.

Mr Foote, finding his health declining, entered into an agreement with Mr Colman, for his patent of the theatre, according to which he was to receive from Mr Colman L.1600 per annum, besides a stipulated sum whenever he chose to perform. Mr Foote made his appearance two or three times in some of the most admired characters; but being suddenly affected with a paralytic stroke one night whilst upon the stage, he was compelled to retire. He was advised to bathe; and accordingly retired to Brighton, where he apparently recovered his former health and spirits, and continued what is called the cock of the company who resorted to that agreeable place of amusement. A few weeks before his death he returned to London; but, by the advice of his physicians, set out with an intention to spend the winter at Paris and in the south of France. He had got no farther than Dover, when he was suddenly attacked by another stroke of the palsy, which in a few hours terminated his existence. He died on the 21st of October 1777, in the fifty-sixth year of his age, and was privately interred in the cloisters of Westminster Abbey. Foote's published dramas, twenty in number, were written in the following order: 1. Taste, a comedy, in 1752; 2. The Englishman in Paris, 1753; 3. The Knights, 1754; 4. The Englishman returned from Paris, 1756; 5. The Author, 1757; 6. The Minor, 1760; 7. The Lyar, 1761; 8. The Orators, 1762; 9. The Mayor of Garrat, 1763; 10. The Patron, 1764; 11. The Commissary; 12. Prelude on opening the Theatre, 1767; 13. The Devil upon Two Sticks, 1768; 14. The Lame Lover, 1770; 15. The Maid of Bath, 1771; 16. The Nabob, 1772; 17. The Bankrupt, 1772; 18. The Cozeners, 1774; 19. A Trip to Calais, 1776; 20. The Capuchin, altered from the former, but prohibited. *Piety in Pattens*, and *The Diversions of a Morning*, altered from *Taste*, were never published. The anonymous mock tragedy entitled *The Tailors* is usually printed with Foote's works, being generally thought to be his composition. Foote borrowed liberally from Molière and others; but what he took without ceremony he generally contrived to make his own by a certain originality in the manner of employing it; and his own humour was so peculiar and effective, that no player has since been equally successful in the parts which he himself performed.

FOP, probably derived from the *vappa* of Horace, applied in the first satire of his first book to the wild and extravagant Nævius, is used amongst us to denote a person who cultivates to excess a regard to adventitious ornament and beauty.

FORAGE, in the military art, denotes hay, oats, barley, wheat, grass, clover, and the like, brought into the camp by the troopers for the sustenance of their horses.

FORBES, DUNCAN, an eminent Scottish lawyer, and Lord President of the Court of Session, was born at Culloden, Inverness-shire, in the year 1685. His natural disposition inclined him to the army; but, as he early discovered a superior genius, he was induced by the advice of friends to apply himself to learning. Having completed his studies at the university of Edinburgh, he removed thence to Utrecht, and afterwards to Paris, where he directed his attention particularly to the civil law, in which he made great progress. He returned to Scotland in 1710, and was the same year called to the bar, where his abilities soon attracted notice, and procured him extensive practice. In 1717 he was appointed solicitor-general of Scotland; in 1722 he was returned member of parliament for the county of Inverness; in 1725 he was made King's Advocate; and in 1742 he attained the highest judicial dignity in Scotland, that of Lord President of the Court of Session. During the rebellion in 1745 and 1746, he was mainly instrumental in preventing a general rising of the Highlanders in favour of the pretender to the crown, and he even mortgaged his estate in support of the government. But the glory he acquired in checking the spread of the insurrection, by preventing some of the most powerful chiefs from joining the standard of Prince Charles Edward, and in afterwards contributing to re-establish peace and order, was the only reward of his services. Although he had impaired, nay almost ruined, his private fortune in the cause of the public, government declined to make him the smallest recompense. The minister of the day, with the meanness for which it is difficult to account, desired to have a state of his disbursements; an incivility which so much shocked the proud spirit of the patriotic president that he withdrew without deigning to make any reply. He had saved the country, yet they wished to huckster with him about pence. His services had been too great to be requited by any ordinary recompense, and hence they repaid him with ingratitude. It seems, also, that he had displeased the government of the day by the freedom and boldness with which he censured the barbarous system pursued, after the battle of Culloden, in a spirit of vindictive ferocity to which there has been no parallel in modern times, excepting, perhaps, in the wars of La Vendée. The ungrateful treatment which he experienced at the hands of the government he had saved is understood to have preyed on the spirits of President Forbes, and to have produced the fever of which he died in 1747, in the sixty-second year of his age. Throughout the whole course of his life he entertained a lively sense of religion, without the least taint of superstition; and his charity was indiscriminately extended to every sect and denomination of religionists. He was well versed in the Hebrew language; and wrote in a flowing style concerning theology and philosophy, particularly respecting the sources of incredulity. His writings, which had no reference to his profession, were, 1. Thoughts on Religion; 2. A Letter to a Bishop; and, 3. Reflections on Incredulity, 1750, in 2 vols. 12mo.

FORBES, *William*, bishop of Edinburgh, was born at Aberdeen in the year 1585, being the son of Thomas Forbes, a respectable citizen descended from Forbes of Corsinday, whose ancestor was the second son of the same Lord Forbes from whom Forbes of Corse derived his lineage. His mother was Janet the sister of Dr Cargill, an eminent physician. From the grammar school, where he had made uncommon progress, he was at the early age of twelve removed to Marischal College, and after the usual period of four years he took the degree of A. M. The principal, Gilbert Gray, was so much pleased with his scholarship and modesty, that he procured his appointment to the professorship of logic. It was his duty to teach the logic of Aristotle, whom he very strenuously defended against the attacks of Ramus. This office he resigned at the expiration of four years, and afterwards prosecuted his theological studies on the continent. Having landed at Dantzig, he travelled through a great part of Prussia and Poland. He studied in several of the universities, particularly those of Helmstädt and Heidelberg. Diligently resorting to the public libraries, he rendered himself familiar with the writings of the fathers and schoolmen; and in the Hebrew language he became a great proficient, or, according to the expression of his biographer, equalled the skill of any Jew. After spending four years in Germany, he went to Holland, and visited the university of Leyden, where his relation Dr Jack was then a professor of philosophy. He was anxious to extend his travels to France and Italy, but being deterred by the delicate state of his health, he sailed for England. From London he proceeded to Oxford, where his learning was held in so much estimation that he was offered the professorship of Hebrew in that university: but his countryman Dr Craig, physician to the king, advised him to consult his health by returning to his native air; and he accordingly arrived at Aberdeen, after an absence of five years, when, according to an obvious calculation, he must have attained the age of twenty-five. The corporation immediately conferred upon him the freedom of the city. When his health was in some measure restored, he was appointed minister of Alford, and was afterwards removed to Monymusk. He speedily acquired the reputation of a most eloquent preacher, and after a short interval he became one of the ministers of Aberdeen. During the king's visit to St Andrews in the year 1617, Forbes was created D. D. As the state of his health was still very infirm, he was willing to exchange his cure for an academical office. He was nominated principal of Marischal College, and discharged his duty with learning and zeal: he not only read lectures in divinity, but likewise taught the Hebrew language. After retaining the office for two years, he was induced to accept of a pastoral charge in Edinburgh, where however he soon discovered that his character and doctrines were held in much less estimation than in his native city. Aberdeen was the strong-hold of episcopacy, and its clergy were among the most learned and respectable of the episcopalians; but in Edinburgh the presbyterians were the predominant party, and Dr Forbes therefore found himself placed in a situation far from agreeable. When he already thought of resigning his living, his old friends at Aberdeen invited him to resume his spiritual labours among them, and there he continued to reside till near the close of his life. When King Charles visited Edinburgh in the year 1633, Forbes was one of those who preached before him; and the king was so much struck with his eloquence, that when he erected the new see, he spontaneously nominated him as the first bishop. His patent bears the date of January 26, 1634. He was consecrated in the month of February, and soon afterwards removed his wife and children to Edinburgh,[1] but he was not long permitted to enjoy his new dignity: he died on the 11th of April, before he had completed the third month of his episcopate, and when he had only attained the forty-ninth year of his age. His remains were interred in the cathedral church of St Giles.

Bishop Forbes was a man of very extensive reading, but he did not himself publish any work. He wrote copious animadversions on the works of Cardinal Bellarmin, and, after his death, these papers came into the possession of Dr Baron, who intended to prepare them for the press; but the national commotions speedily ensued, and this design was never executed, nor has their subsequent fate been ascertained. These animadversions, which his biographer describes as elaborate and nervous, filled the margin of the cardinal's works, printed at Paris in three volumes. Twenty-four years after the author's death, Thomas Sydserf, bishop of Galloway,[2] published "Considerationes modestæ et pacificæ Controversiarum de Justificatione, Purgatorio, Invocatione Sanctorum et Christo Mediatore, Eucharistia, per Gulielmum Forbesium, S. T. D. et Episcopum Edinburgensem primum. Opus posthumum, diu desideratum." Lond. 1658, 8vo. The preface, subscribed T. G., that is, Thomas Gallovidiensis, is followed by an account of the author's life. This volume, which was reprinted at Helmstädt in the year 1704, attracted a very considerable degree of attention, and is mentioned by many of the continental writers.[3] Any honest plan for promoting peace may seem to merit praise; but it is a very indifferent method of securing the peace of the church, by offering to meet the papists half-way. This is reforming backwards. The character of the learned author has thus been drawn by Bishop Burnet: "He was a grave and eminent divine: my father, that knew him long, and being of council for him in his law-matters, had occasion to know him well, has often told me, that he never saw him but he thought his heart was in heaven, and he was never alone with him but he felt within himself a commentary on these words of the apostles, 'Did not our hearts burn within us, while he yet talked with us, and opened to us the Scriptures?' He preached with a zeal and vehemence, that made him forget all the measures of time, two or three hours was no extraordinary thing for him; those sermons wasted his strength so fast, and his ascetical course of life was such, that he supplyed it so scantly that he dyed within a year after his promotion; so that he only appeared there long enough to be known, but not long enough to do what might have been otherwise expected from so great a prelate. That little remnant of his that is in print shews how learned he was. I do not deny but his earnest desire of a general peace and union among all Christians has made him too favourable to many of the corruptions in the church of Rome: but tho' a charity that is not well ballanced may carry one to very indiscreet things, yet the principle from whence they flowed in him was so truly good, that the errors to which it carried him ought to be either excused, or at least to be very gently censured."[4] (x.)

Forbes, *John*, one of the most learned divines whom Scotland has produced, was born on the second of May 1593. He was the descendant of an ancient and opulent family: his father was Patrick Forbes, bishop of Aberdeen, his mother was Lucretia the daughter of David Spence of Wormiston. His paternal ancestor was a younger son of Lord Forbes, and he was thus connected with some of the principal families in his native district.

Patrick Forbes was the eldest son of William Forbes of Corse and Oneill in the county of Aberdeen. William, the second son, bequeathed to his posterity the estates of Craigievar and Fintray. John, the third son, became minister of Alford, and, adhering with great zeal to the presbyterian discipline, was at length driven into exile on account of his having acted as moderator of the Aberdeen assembly. He settled in Holland, and successively officiated as a clergyman at Middelburg and Delft. His son Patrick Forbes quitted the presbyterians, and became bishop of Caithness in the year 1662. William's fourth son was Sir Arthur Forbes of Castle Forbes in the kingdom of Ireland, whose son was created earl of Granard: the father followed the profession of arms, and after quitting the Swedish service, had obeyed the call of fortune in Ireland, where he acquired an ample estate. The bishop of Aberdeen had other three brothers, of whom no particular notices have been preserved. He was himself educated at Stirling school, under Thomas Buchanan, an eminent classical master, and afterwards became a student in the university of Glasgow, where he was committed to the care of his distinguished kinsman Andrew Melville. When this learned man removed to St Andrews, in the year 1580, he was accompanied by Forbes, who applied himself to the study of the Hebrew language and of divinity with so much assiduity and success, and was so conspicuous for the propriety and gravity of his deportment, that a design was entertained of appointing him to a professorship in St Mary's College; but his father, who was already advanced in years, was anxious to see the heir of his estates otherwise settled, and, in compliance with this wish, the son relinquished his academic life. After his marriage, he fixed his residence near Montrose, and gained the respect of all his neighbours. Nor were his religious exercises confined to his own family: several of the churches in that vicinity were deprived of their pastors, and in one of these he regularly officiated for some time, till he was strongly urged by the bishop of the diocese, as well as by many other clergymen, to enter into holy orders. He was however unwilling to comply with this requisition, and the archbishop of St Andrews, who did not approve of lay-preaching, enjoined him to desist from the discharge of clerical functions. After a certain interval, which is not clearly defined, he consented to take orders, and was appointed parson of Keith, in the diocese of Moray. In the year 1618, he was elected bishop of Aberdeen, and he appears to have been one of the most exemplary prelates of that age. He was, says Bishop Burnet, "a gentleman of quality and estate, but much more eminent by his learning and piety, than his birth or fortune could make him. He had a most terrible calamity on him in his family, which needs not be named: I do not know whether that or a more early principle determined him to enter into orders: he undertook the labour of a private cure in the country, upon the most earnest invitations of his bishop, when he was forty-eight years old, and discharged his duty there so worthily, that within a few years he was promoted to be bishop of Aberdeen; in which see he sat about seventeen years. It was not easie for King James to perswade him to accept of that dignity, and many months passed before he could be induced to it, for he had intended to have lived and dyed in a more obscure corner. It soon appeared how well he deserved his promotion, and that his unwillingness to it was not feigned, but the real effect of his humility. He was in all things an apostolical man; he used to go round his diocess without noise, and but with one servant, that so he might be rightly informed of all matters. When he heard reports of the weakness of any of his clergy, his custome was to go and lodge unknown near their church on the Saturday night, and next day, when the minister was got into the pulpit, he would come to church, that so he might observe what his ordinary sermons were, and accordingly he admonished or encouraged them. He took such care of the two colledges in his diocess, that they became quickly distinguished from all the rest of Scotland: so that when the troubles in that church broke out, the doctors there were the only persons that could maintain the cause of the church; as appears by the papers that past between them and the covenanters. And though they begun first to manage that argument in print, there has nothing appeared since more perfect than what they writ. They were an honour to the church both by their lives and by their learning, and with that excellent temper they seasoned that whole diocess, both clergy and laity, that it continues to this day very much distinguished from all the rest of Scotland, both for learning, loyalty and peaceableness." Bishop Forbes is the author of several works, which deserve to be mentioned. The most considerable of them appear in a volume bearing the subsequent title: "An learned Commentarie vpon the Revelation of Saint Iohn, wherein both the covrse of the whole booke, as also the more abstruse and hard places thereof, are more cleerly and euidently explaned then heretofore they haue bene. Newly corrected, and the defectes and errors of the first edition supplied and amended. By Patrick Forbes of Cotharis. Wherevnto is added an profitable Treatise of the author, in defence of the lawfull Calling of the Ministers of Reformed Churches, against the Cauillations of Romanistes: and an Epistle to a Recusant, cleering and maintayning some pointes of the said Treatise, chalenged by a Roman Elymas Bar-Iesus-it." Middelburg, 1614, 4to. Of these different works a Latin translation was long afterwards published by his son Dr Forbes: "Commentarius in Apocalypsin, cum Appendice," &c. Amstelodami, 1646, 4to. Another work of the bishop is entitled "Eubulus, or a Dialogve, wherein a rugged Romish Ryme (inscrybed, *Catholicke Questions to the Protestant*) is confuted, and the Questions there-of answered. By P. A." Aberdene, 1627, 4to.

Of this worthy father, John Forbes was the second son. After having studied at Aberdeen, he was sent to the university of Heidelberg, where he was placed under the care of David Pareus, an eminent professor of divinity. He likewise prosecuted his studies at Sedan, and in some other universities which are not specified. Having devoted much time and labour to the acquisition of the Greek and Hebrew languages, and of all the variegated knowledge requisite for a theologian, he returned to his native country in 1619, being then in the twenty-sixth year of his age, and on the 27th of April he was admitted professor of divinity in King's College, Aberdeen. In this important vocation he laboured with great diligence, and speedily acquired the character of a most able and useful teacher. He was profoundly skilled in ecclesiastical antiquity; and, not contented with delivering what is called a system of divinity, he exhibited a very elaborate deduction of the progress of Christian doctrine in various ages of the church. Of the value of his instructions in this department, a very adequate opinion may be formed from the inspection of a work which he published in the maturity of his learning and judgment. Nor did he neglect to instruct his students in practical religion: one division of his lectures related to moral theology, another to the pastoral care and to residence.

While he was engaged in these useful and honourable labours, the kingdom was agitated by religious dissensions. Episcopacy, commonly described by the more odious name of prelacy, was no favourite with the great body of the people; and the five articles of Perth, passed in 1618, and relating to kneeling at the communion, the observance of festivals, confirmation, private baptism, and private communion, had excited a violence of opposition with which it was found very difficult to contend. Dr Forbes, who was as much distinguished by his piety as by his learning, endeavoured to promote peaceable measures; and with this view, he published his earliest work, bearing the title of "Irenicum Amatoribus Veritatis et Pacis in Ecclesia Scoticana." Aberdoniæ, 1629, 4to. Of this work he sent a copy to Archbishop Usher, who received it with much cordiality.[1] The bishop of Aberdeen did not live to witness the subversion of episcopacy: he died on the 28th of March 1635, in the seventy-first year of his age. As his eldest son had died ten years before, the professor of divinity succeeded to the family-estates. This prelate being regarded as the restorer of the university, and as a great pillar of the church, his death was sincerely lamented by the adherents of his own party. Soon after his decease, a volume, consisting of 429 pages, and including a portrait, was published under the following title: "Funerals of a Right Reverend Father in God, Patrick Forbes of Corse, Bishop of Aberdeen. Τοῦ ἐν ἁγίοις Reverendissimi in Christo Patris, Patricii Forbesii a Corse, Episcopi Abredoniensis, Tumulus, a multis omnium ordinum collachrymantibus variegato opere exornatus." Aberdene, 1635, 4to. Among other contributions, this volume includes English sermons by Dr Baron, Dr Scrogie, Dr Guild, Dr Sibbald, and Dr Ross, and a funeral oration in Latin by David Leitch, sub-principal of King's College. Besides Latin verses, Dr Forbes contributed a Latin sermon, and a "Dissertatio de Visione Beatifica." Among the contributors of Latin verses we find Robert Gordon of Straloch, Arthur Johnston, David Wedderburn, Patrick Panter, George Wishart, and Andrew Ramsay. The Latin and English or Scotish verses are numerous; and there is a Greek tetrastich by Robert Downie, the librarian of King's College.

---

[1] See the Letters (p. 456.) subjoined to Dr Parr's Life of Usher. Lond. 1686, fol.

Dr Forbes, who was naturally disposed to think that nothing is better than peace,[1] next published "A peaceable Warning to the Subjects in Scotland; given in the yeare of God 1638." Aberdene, 4to. It was speedily answered in a tract ascribed to Calderwood, the most strenuous defender of the presbyterian cause. The introduction of the covenant involved the most conscientious of the episcopalians in inextricable difficulties. The professors and ministers of Aberdeen, who had recourse to argument and remonstrance, printed a paper containing "Generall Demands concerning the late Covenant." To this paper, which was subscribed by six doctors of divinity, Forbes, Scrogie, Lesley, Baron, Sibbald, and Ross, an answer was returned under the names of Alexander Henderson, David Dickson, and Andrew Cant, three individuals of no small influence among the covenanters. The doctors of Aberdeen subjoined replies to the answers; which produced further answers from Henderson and Dickson. The doctors published a rejoinder, and had the advantage of the last word;[2] but this was the chief advantage which they obtained, for all of them were deprived of their offices in the church and university, for their refusal to subscribe the covenant. William Lesley was principal of King's College, and appears to have been a man of erudition.[3] Robert Baron, a younger son of Baron of Kinnaird in the county of Fife,[4] was professor of divinity in Marischal College, and one of the city clergy. Being a great master of scholastic philosophy and theology, he published various works which procured him a high reputation, and he is described as "a person of incomparable worth and learning."[5] He was elected bishop of Orkney, but he died at Berwick in 1639, before he could be consecrated. Like Dr Lesley, he had been deprived of his office, and had been obliged to fly from Aberdeen. His brother Dr John Baron, professor of divinity at St Andrews, was finally induced to subscribe the covenant. Dr Forbes was treated with some degree of tenderness; and the covenanters being solicitous to gain such a convert, the proceedings against him in the ecclesiastical courts were protracted for several years. After some preliminary steps, he was in 1640 cited to appear at Aberdeen before a delegation of the general assembly. He was declared to be free from the taint of popery and Arminianism; but as he still adhered to episcopacy, and declined to subscribe the covenant, his case, through the influence of Baillie, was remitted to the presbytery of Edinburgh. He was allowed a month to yield satisfaction to this judicatory, and as he failed to do so, sentence of deprivation was pronounced against him. In 1643 he moved the synod of Aberdeen to make application to the general assembly, that he might be permitted to retain his professorship without subscription; but it was there determined that his deprivation was valid from the beginning.[6] He had purchased two houses adjoining to the college, and had assigned one of them to the professor of divinity, and the other to the *cantor*, a person on the foundation. In the deed of conveyance, he neglected to reserve to himself a life-rent in the professor's house; nor can it be mentioned without regret and indignation that he was obliged to vacate it for his successor in office.[7]

He was anxious to continue his residence in the university, for the benefit of prosecuting his researches in the public libraries; but he found that he must either subscribe the solemn league and covenant, or abandon his native country. Preferring the latter alternative, he embarked for Holland on the 5th of April 1644, and, after a voyage of five days, landed at Campvere. He travelled through the different provinces, and frequently preached in the Scotish and English churches. He had formerly married a lady of Middelburg, named Soete Roos-boom, who died on the 19th of January 1640. She was the mother of nine children; but only one of them, a son named George, was alive at the time of the father's exile. Dr Forbes chiefly resided at Amsterdam, and occupied himself in preparing for the press a work of great research and value. It appeared under the title of "Instructiones Historico-Theologicæ de Doctrina Christiana, et vario Rerum Statu, ortisque Erroribus et Controversiis, jam inde a temporibus Apostolicis ad tempora usque seculi decimi-septimi priora." Amst. 1645, fol. A second edition followed after a considerable interval. Genevæ, 1680, fol. And an abridgement of the work was published by Arnoldus Montanus, under the title of *Forbesius contractus*. Amst. 1663, 8vo. Forbes was enabled to prefix to his ample volume the favourable judgment of the theological faculties of Leyden, Utrecht, and Franeker, as well as that of Rivet, Maresius, and Vossius. This book established the reputation of the author as a theologian of a very high rank. Bishop Burnet speaks of it as "a work which, if he had finished it, and had been suffered to enjoy the privacies of his retirement and study, to give us the second volume, had been the greatest treasure of theological learning that perhaps the world has yet seen."[1] Dr Cave has likewise mentioned it as a work of great value,[2] and it has received similar commendation from writers of many different nations.

[2] The generall Demands of the reverend Doctors of Divinitie, and Ministers of the Gospell in Aberdene, concerning the late Covenant in Scotland; together with the Answeres, Replyes, and Duplyes that followed thereupon, in the year 1638. Reprinted in one book, by order of Parliament. Aberdene, 1663, 4to.

[3] See Garden, Vita J. Forbesii, p. 25.—In a letter dated in 1702, Bishop Sage conveys the following information: "The demands, replys, and duplys of the Doctors of Aberdeen, as I was informed when there, though subscribed by six, wer all formed and digested by Dr Lesley." (Catalogues of Scotish Writers, p. 131.) Middleton has however stated that Dr Baron "bare the greatest share in that famous debate."

[4] Sibbald's History of Fife and Kinross, append. Edinb. 1710, fol.

[5] Middleton's Appendix to Spotswood's History, p. 29.—Baillie, vol. i. p. 185, characterizes him as good Dr Baron. He subjoins, "I had great hopes, if he had lived a little, he should have quit them, and been glad to embrace the covenant of his mother church, as his learned brother now has done." Middleton speaks of John Baron as "a person of great worth and learning, and of great candour. He died in the time of our late combustions."

[6] Baillie's Letters and Journals, vol. i. p. 383.

[7] Spalding's Hist. of the Troubles in Scotland, vol. ii. p. 161. 190. Orem's Description of King's College, p. 84. 142.

After having resided upwards of two years in Holland, Forbes embarked at Campvere on the 8th, and arrived at Aberdeen on the 14th of July 1646. He immediately retired to his country-seat at Corse, and was permitted to spend the remainder of his days in learned and devout seclusion. He died on the 29th of April 1648, having completed the fifty-fifth year of his age. A short time before his death, he made application to the presbytery for permission to have his bones deposited in Bishop Dunbar's aisle in the cathedral church, beside those of his father and wife; but even this last favour was denied to a learned and excellent man, whose fault was a difference of opinion on the subject, not of Christian doctrine, but of ecclesiastical polity. He then directed his body to be interred in the churchyard of Leochel, where no monument was erected to his memory.[3] He left an only son, who is described by Dr Garden as the heir of his father's estates, but not of his virtues.

Dr Forbes was small in stature, and of a somewhat swarthy complexion. A person who had acquired such ample stores of erudition must have been an ardent and indefatigable student; and, with respect to his habits of study, we are informed that he always read and wrote in a standing posture. One of the few relaxations in which he indulged was the Scottish game of golf. With his extensive learning he united fervid and habitual piety. His conduct was upright and consistent in times of no small difficulty and distress.

An honourable monument was at length erected to his memory, in a collective edition of his Latin works. "Reverendi viri Johannis Forbesii a Corse, Presbyteri et SS. Theologiæ Doctoris, ejusdemque Professoris in Academia Aberdonensi, Opera omnia, inter quæ plurima posthuma, reliqua ab ipso auctore interpolata, emendata atque aucta." Amstelædami, 1703, 2 tom. fol. The second volume bears the date of 1702. The edition is introduced by two dedications, written by George Garden, D.D., an advertisement by Wetstein the printer, and a preface by Dr Gürtler, professor of divinity at Deventer. A copious life of the author, by Dr Garden, is next subjoined. The biographer, who appears to have been a very amiable man, was a regent in King's College, and afterwards minister of St Machar's, but was ejected from his living on the restoration of the presbyterian discipline. Under the title of "J. Forbesii Vita interior," he has added an abstract of Forbes's diary, which was written in English. One of the posthumous works is an ample treatise, entitled "Theologiæ Moralis libri decem; in quibus Præcepta Decalogi exponuntur, et variæ circa Dei Legem, et specialia ejusdem Præcepta, Controversiæ dissolvuntur, et Casus Conscientiæ explicantur." (x.)

FORCE, in *Philosophy*, denotes the cause of the change in the state of a body, when, from being at rest, it begins to move, or has a motion which is either not uniform or not direct. Whilst a body remains in the same state, either of rest or of uniform and rectilinear motion, the cause of its remaining in such a state is in the nature of the body, and it cannot be said that any extrinsic force has acted on it. This internal cause or principle is called *inertia*. See MECHANICS and PHYSICS.

FORCEPS, in *Surgery*, a pair of scissors for cutting off, or dividing, the fleshy membranous parts of the body, as occasion requires.

FORCER, in *Mechanics*, is properly a piston, without a valve. For by drawing up such a piston, the air is drawn up, and the water follows; and by pushing the piston down again, the water, being prevented from descending by the lower valve, is forced up to any height by means of a side branch.

FORCHEIM, a bailiwick of the circle of the Upper Maine, in the kingdom of Bavaria, extending over eighty-eight square miles. It contains one city, one market-town, and forty-one villages, with 11,500 inhabitants. It is an undulating country, productive in corn and pasture, and yielding some wine. The capital, of the same name, is a city situated on the river Regnitz, and containing 396 houses, with 3230 inhabitants, who have large breweries, paper-mills, glass-houses, tanneries, and iron forges at work.

FORDINGBRIDGE, a market-town of Hampshire, in the hundred of its own name, ninety-two miles from London. It is situated on the river Avon, on the borders of the New Forest. There are some manufactures of printed linen and calico. The market is held on Friday. The population amounted in 1801 to 2335, in 1811 to 2259, in 1821 to 2444, and in 1831 to 2611.

FORDUN, JOHN, the venerable father of Scottish history, apparently derives his surname from a village in the county of Kincardine, where he is supposed to have been born. He was not, as he has sometimes been represented, a monk, but a secular priest; and in some manuscripts of his history, he is described as a chaplain of the cathedral of Aberdeen; a title which Goodall seems to have considered as equivalent to canon. Bower describes him as a simple man, who had never graduated in the schools. He was engaged in the composition of his work towards the close of the fourteenth century. The first five books, and twenty-three chapters of the sixth book of the Scotichronicon, are the composition of Fordun: for the remainder of the work in its present form, we are indebted to Walter Bower, who was born at Haddington in the year 1385, and was unanimously elected abbot of St Colm in the year 1418. This monastery, situated in a small island in the Firth of Forth, belonged to the canons regular of St Augustin. The abbot is sometimes called Bowmaker, which is equivalent in signification to Bower. From 1395 to 1399 John Bowmaker appears as the deputy of the bailies or of the *customars* of Haddington, at the presentation of their accounts.[4] As the first of these dates is only ten years subsequent to the abbot's birth, and as he was a native of that town, this individual might possibly be his father or other relation. At the request of Sir David Stewart of Rossyth, he undertook to transcribe the papers of Fordun; but instead of executing a mere transcript, he inserted large interpolations, and continued the narrative to the death of James the First, having thus extended the work to sixteen books. Of this continuation the principal materials had however been collected by his predecessor. Bower professes to have been careful to distinguish what belonged to each; but as the negligence of subsequent copyists has omitted all his marks, we must chiefly be guided by the internal evidence in adjusting their respective claims. The Latinity of the Scotichronicon, though certainly far from being classical, is less barbarous than that of many other chronicles of the middle ages. Winton, the author of a chronicle in Scottish verse, is perhaps a more judicious writer than either Fordun or Bower, though his share of credulity and superstition is by no means inconsiderable. Beyond this period we have scarcely any records professedly historical, except the Chronicle of Melrose, and a few other fragments, neither considerable for their value nor extent.

[1] Burnet's Life of Bedell, pref.

[2] Cave, Historia Literaria, p. xxx.

[3] Orem's Description of King's College, Aberdeen, p. 85.

[4] Accounts of the Great Chamberlains of Scotland, vol. ii. p. 290. 314. 360. 426.

It would be endless, as Nicolson has remarked, "to compute into how many several chronicles this of Fordon's has been multiply'd: for, being in every monastery of the kingdom under the anonymous title of *Scoto-chronicon*, it commonly borrowed a sirname from the place to which it belong'd."[1] The Black Book of Scone, and the Black Book of Paisley, were copies which obtained no small celebrity, and which seem to have been commonly regarded as two distinct chronicles compiled in those two monasteries. Thus, the Book of Pluscardine was a copy belonging to the priory of that name. Magnus Maccullooch and Patrick Russell, who are sometimes mentioned as continuators, were in all probability little more than transcribers of Fordun.

Some portions of the Scotichronicon were inserted in the collection of Dr Gale,[2] who obtained a defective copy, which he supposed to have belonged to Hector Boyce. In the year 1719, Richard Hay, a canon regular of St Augustin, issued "Proposals for Printing the Chronicle of John Fordun, with the Additions and Continuation of Walter Bowmaker, Abbot of Inch-Colm, containing the memorable things which happened in every year, since our first rise, to King James the First's death; conform to an authentick manuscript, belonging of old to one of our decay'd monasteries: with several notes, for clearing the dark parts of our history." The manuscript, "a large folio, written in old, but in glorious characters," belonged to the Cistertian monastery of St Mary at Cupar in Angus: it afterwards came into the possession of Hay, and is now deposited in the Advocates Library. He concludes his Proposals in the following manner: "Many persons of an eminent character have appeared desirous to have it printed, because what copies thereof were carried to England, France, Flanders, Italy, and elsewhere, during the heat of the Reformation, or our late disturbances, are properly lost for us. And what remain in the country, in private hands or in particular libraries, are of no use to the publick, whilst they are shut up, and as if it were hidden in obscure places, where scarce any number of men of an ordinar capacity are allowed access. Therefor I have been willing to publish this manuscript, with several notes, for the greater intelligence of our history, and a large preface, where I shall give an exact account of the fate and fortune of the most part of the others, transcribed by different hands, in former ages, with whom I have compared this original. The charges and expences of publishing this book will be certainly considerable. So those that are pleased to further and incourage this enterprize, are desired to pay ten shillings sterling at subscribing, and as much at the delivery of the printed copy, which will prove a good folio, on fine paper, and in good caracters, and will consist of 160 sheet and above. Their names and designations shall be insert in the front, and their respective houses or families shall be kindly remembered in the notes. As to the subscriptions, they are to be taken by the author, at his lodging in Howison's Land in the Potterraw; by Mr John Mackenzie of Delvin, at his lodging in the Parliament Close; by Mr Henry Massie, merchant, near the foot of Blackfriar-Wynd; by Mr William Adams, printer, over against the Trone-Church; by Mr Ruddiman in the Advocates Library; who shall deliver to the persons concerned the author's obligation to have the compleat copy remitted to them about the end of the following year, 1720, they paying ten shillings more at the time appointed." This plan was never carried into execution; but a valuable edition was soon afterwards published by Hearne, under the title of "Johannis de Fordun Scotichronicon genuinum, una cum ejusdem Supplemento ac Continuatione." Oxon. 1722, 5 tom. 8vo. The editor proceeds upon the plan of separating the interpolations of Bower from the text of Fordun. After an interval of nearly forty years, another edition was published by Walter Goodall, assistant-keeper of the Advocates Library: "Joannis de Fordun Scotichronicon, cum Supplementis et Continuatione Walteri Boweri, Insulæ Sancti Columbæ Abbatis." Edinb. 1759, 2 tom. fol. Goodall chiefly adheres to an excellent manuscript, written on vellum, and preserved in the library of the university of Edinburgh. (x.)

FORDYCE, David, professor of moral philosophy in Marischal College, Aberdeen, was born in that city in 1711. Having received the early part of his education at the grammar school, he, at the age of thirteen, entered the Greek class in Marischal College, Aberdeen; in 1728 he took the degree of master of arts, and in 1742 he was admitted professor of philosophy in the same college. Being originally designed for the church, he applied himself with great ardour to the study of divinity, in which he made great progress, though he never became a settled minister in the establishment of his native country. That he was well qualified to be such, however, appears from his *Theodorus*, a dialogue concerning the art of preaching, which he afterwards published. In 1750 he went abroad on his travels, in order to obtain fresh stores of knowledge; but after a successful tour through several parts of Europe, he was, on his return home, unfortunately cast away in a storm on the coast of Holland, in the forty-first year of his age. Besides the above work, he wrote *Dialogues on Education*, 8vo, and a Treatise on Moral Philosophy, published in the *Preceptor*. The third edition of his *Theodorus* was published in London, after his death, by his brother James, the subject of the following article.

Fordyce, *James*, a Scottish clergyman of considerable eminence, was born at Aberdeen in the year 1720. He received his classical education at the public grammar school, and afterwards entered Marischal College, where he went through the course of studies necessary to qualify him for being a minister of the gospel. His natural abilities were excellent, and having improved to the utmost the favourable opportunities he enjoyed at the university, he was considered as qualified for becoming a preacher of the gospel at an early period of life. His first appointment was that of second minister of Brechin, in the county of Angus, after which he accepted of a call to Alloa, near Stirling. The people of this parish were prepossessed in favour of another, and prejudiced against Mr Fordyce, which could not fail to prove an unpleasant circumstance; yet by his impressive delivery, and indefatigable attention to every part of his ministerial duty, he soon overcame their prejudice, and acquired their esteem and admiration.

During his residence at Alloa, he attracted the notice of the public by three sermons; the first on the eloquence of the pulpit, the second on the method of promoting edification by public institutions, and the third on the delusive and sanguinary spirit of popery, preached before the synod of Perth and Stirling. But still greater admiration was excited by his sermon on the folly, infamy, and misery of unlawful pleasure, preached before the general assembly of the church of Scotland in 1760. About this time the university of Glasgow conferred upon him the degree of doctor of divinity, probably on account of the fame he had acquired by this sermon.

---

[1] Nicolson's Scottish Historical Library, p. 92.

[2] Historiæ Britannicæ Scriptores XV. vol. i. p. 565.

The friends of Dr Fordyce being mostly in the metropolis, he was invited to become the colleague of Dr Lawrence, minister of a respectable congregation in Monkwell Street, London, on whose death, which happened a few months afterwards, Dr Fordyce became once more celebrated for his pulpit eloquence, generally preaching to overflowing audiences. The best specimen of pulpit eloquence which perhaps proceeded from his pen was delivered at the ordination of Mr James Lindsay, who, after he declined officiating as a minister, became his successor. The remainder of his life he spent chiefly in retirement in Hampshire, in the vicinity of the residence of Lord Bute, with whom he lived in the greatest intimacy, and to whose valuable library he had unlimited access. He afterwards went to Bath, where he suffered much from an asthmatic affection, which he bore with the fortitude of a Christian, and expired without a groan on the first of October 1796, in the seventy-sixth year of his age.

The doctor's writings discover much genius and a correct taste, extensive knowledge of the world, and a happy method of engaging the attention. He was the author of 1. Sermons to Young Women, 1765, in 2 vols. 12mo; 2. A sermon on the Character and Conduct of the Female Sex; 3. Addresses to Young Men, 1777, in 2 vols. 12mo; 4. Addresses to the Deity, 1785, in 12mo; 5. A volume of Poems; 6. A discourse on Pain, 1791; and Additions to his brother's Temple of Virtue.

FORDYCE, *George*, a writer and lecturer on medicine, was born at Aberdeen in 1736, and studied at the university of that city, where he took the degree of master of arts at the early age of fourteen, perhaps not altogether owing to the superiority of his genius, or the extent of his acquirements, which could not be very extraordinary in a boy of his years. He became apprentice to an uncle who practised surgery at Uppingham in Rutlandshire, when he was only fifteen; and afterwards went to the university of Edinburgh, where his diligence and progress attracted the attention of Dr Cullen, at that time professor of chemistry, who very generously promoted his improvement. He graduated in 1758, when only twenty-two years of age; after which he resided during one winter at Leyden. The greater part of his patrimony having been spent on his education, he resolved to try his fortune in London, where he settled in the year 1759. He commenced with a course of lectures on chemistry; and although his encouragement at first was by no means flattering, yet he steadily and diligently persevered, notwithstanding unfavourable appearances, till his literary merit began gradually to be discovered and appreciated. A number of young men who came to study in London did not think that their medical course was complete without availing themselves of the benefit of his course of lectures. In the year 1768 he published his *Elements of the Practice of Physic*, which formed the text-book of his medical course, and were much read as a valuable epitome of medicine. His private practice was very respectable; and in the year 1770 his medical reputation was so great that he was chosen physician to the hospital of St Thomas, although he had to contend against a gentleman with very powerful interest; whilst his merit as a man of science procured him admission as a member of the Royal Society in 1776. In 1787 he was chosen a fellow of the College of Physicians; and his chemical knowledge was of much importance to that body in preparing a new edition of their Pharmacopœia. By the influence of his connections, but probably more so by his literary reputation, he was appointed to furnish the navy with sour krout, which we believe he executed with advantage both to himself and to the public. By this time, however, his constitution had discovered symptoms of premature decay; yet he continued to discharge his professional duties till he fell a victim to an irregular gout, and water in the chest, on the 25th of June 1802, in the sixty-sixth year of his age. If his lectures wanted the charms of an eloquent delivery, he made amends by the originality of his ideas and the extent of his scientific information. His works are, 1. Elements of Agriculture and Vegetation; 2. Elements of the Practice of Physick; 3. A Treatise on the Digestion of Food; 4. Four Dissertations on Fever, to which has been added a fifth, published from his manuscript since his death. His other works appeared in the *Philosophical Transactions*, to which he contributed eight papers, and on the *Medical and Chirurgical Transactions*, to which he contributed three.

FORECASTLE OF A SHIP, that part where the foremast stands. It is divided from the rest by a bulkhead.

FOREIGN, something extraneous, or that comes from abroad. The word is formed from the Latin *fores*, doors; or *foris*, out of doors; or *forum*, the market-place.

FOREIGNER, the natural-born subject of some foreign prince. Foreigners, though made denizens, or naturalized, are disqualified from bearing any office in government, being of the privy council, or members of parliament, &c. This is by the acts of the settlement of the crown.

FOREJUDGER, in *Law*, signifies a judgment by which one is deprived or put by a thing in question.

FORELAND, or FORENESS, in *Navigation*, a point of land jutting out into the sea.

North FORELAND, in the Isle of Thanet, Kent, of which it is the north-eastern point, is the promontory ascertained by act of parliament to be the most southern part of the port of London, which is thereby extended north in a right line to the point called the Nase on the coast of Essex, and forms what is properly called the Mouth of the Thames. A sea-mark was erected here by the Trinity-house corporation, at the public expense. All vessels which pass on the south side of this head-land are said to enter the Channel; and all the towns or harbours between London and this place, whether on the Kentish or Essex shore, are called members of the port of London.

South FORELAND, in Kent, a head-land forming the eastern point of the Kentish shore; and called *South*, in respect to its bearing from the *North* Foreland, which is about six miles to the north. Its situation is a great security to the Downs, the road between both, which would be very dangerous for ships, did not this point break off the sea, which would otherwise come rolling up from the west to the Flats; so that these two capes breaking all the force of the sea on the south-east and south-west, make the Downs be accounted a good road, excepting when the wind blows excessively hard from south-east, east-by-north, or east-north-east, when ships in the Downs are driven from their anchors, and often run ashore, or are forced on the sands, or into Sandwich Bay, or Ramsgate Pier.

FORE-LOCKS, in nautical language, little flat wedges made of iron, used at the end of bolts, to keep them from flying out of their holes.

FOREMAST OF A SHIP, a large round piece of timber, placed in her fore part or forecastle, and carrying the fore-sail and fore-top-sail yards. Its length is usually eight ninths of the main-mast, and the fore-top-gallant mast is half the length of the fore-top.

FOREST, in *Geography*, a large extent of ground covered with trees. The word is formed from the Latin *foresta*, which first occurs in the capitulars of Charlemagne, and which is itself derived from the German *frost*, signifying the same thing. Spelman derives it from the Latin *foris restat*, by reason forests are out of towns. Others derive *foresta* from *feris*, that is, *Foresta, quod sit tuta statio ferarum*, as being a safe station or abode for wild beasts.

The Caledonian and Hercynian forests are famous in history. The former was a celebrated retreat of the ancient

Picts and Scots; and the latter, in Cæsar's time, extended from the borders of Alsatia and Switzerland to Transylvania, being computed at sixty days' journey in length, and nine in breadth. The ancients venerated forests, and imagined that a great part of their gods resided therein. Temples were frequently built in the thickest forests, the gloom and silence of which naturally inspire sentiments of devotion. For a similar reason the Druids made forests the place of their residence, performing sacrifices, instructing youth, and giving laws in their umbrageous recesses.

Forest, in *Law*, is defined, by Manwood, a certain territory of woody grounds and fruitful pastures, privileged for wild beasts and fowls of forest, chase, and warren, to rest and abide under the protection of the king, for his princely delight; bounded with unremoveable marks and meres, either known by matter of record or prescription; replenished with wild beasts of venery or chase, with great coverts of vert for the said beasts; and for preservation and continuance whereof, the vert and venison, there are certain particular laws, privileges, and officers. Forests are of such antiquity in England that, excepting the New Forest in Hampshire, erected by William the Conqueror, and Hampton Court, erected by Henry VIII. it is said that there is no record or history which makes any certain mention of their erection, though they are mentioned by several writers and in several of our laws and statutes. Ancient historians tell us that New Forest was raised by the destruction of twenty-two parish churches, and many villages, chapels, and manors, for the space of thirty miles together, which was attended with divers judgments on the posterity of William I. who erected it: for William Rufus was there shot with an arrow, and before him Richard the brother of Henry I.; and Henry, nephew to Robert, the eldest son of the conqueror, was, like Absalom, suspended by the hair of the head in the boughs of the forest.

A forest in the hands of a subject is properly the same thing as a *chase*, being subject to the common law, and not to the forest laws. But a chase differs from a forest in this, that it is not enclosed, and likewise, that a man may have a chase in another man's ground as well as his own, that is, the liberty of keeping beasts of chase or royal game therein, protected even from the owner of the land, with a power of hunting them thereon.

The manner of erecting a forest is this: Certain commissioners are appointed under the great seal, who view the ground intended for a forest, and fence it round; and this commission being returned into chancery, the king causes it to be proclaimed throughout the country where the land lies, that it is a forest, prohibiting all persons from hunting therein without his leave. Though the king may erect a forest on his own ground and waste, he may not do it on the ground of other persons without their consent; and agreements with them for that purpose ought to be confirmed by parliament.

A forest, strictly speaking, cannot be in the hands of any but the king; for no person except the king has power to grant a commission to be justice in eyre of the forest. Yet, if he grants a forest to a subject, and that on request made in the chancery, such subject and his heirs shall have justices of the forest; in which case the subject has a forest in law.

Forest-Laws, are peculiar laws, different from the common law of England. Before the making of the *Charta de Foresta*, offences committed therein were punished at the pleasure of the king in the severest manner. By this charter many forests were disforested and stripped of their oppressive privileges, and regulations were made for the government of those which remained; in particular, killing the king's deer was declared to be no longer a capital offence, but only punishable by fine, imprisonment, or abjuration of the realm. Yet even in this charter there were some grievous articles, which the clemency of later princes has since thought fit to alter *per assisas forestæ*. And to this day, in trespasses relating to the forest, *voluntas reputabitur pro facto*; so that if a man be taken hunting a deer, he may be arrested as if he had taken a deer.

FORESTALLING, in *Law*, buying or bargaining for any corn, cattle, victuals, or merchandise, when on the way to fairs or markets to be sold, before they get thither, with an intent to sell the same again at a higher price.

FORESTER, a sworn officer of the forest, appointed by the king's letters patent, to walk the forest at all hours, and watch over the vert and venison; also to make attachments and true presentments of all trespasses committed within the forest.

FORFAR, a county in Scotland, bounded by the shires of Aberdeen and Kincardine on the north, the German Ocean on the east, the Frith of Tay, which separates it from Fife, on the south, and the county of Perth on the west. It is situated between 56° 27′ and 57° north latitude, and between 2° 28′ and 3° 22′ west longitude from Greenwich, and extends from north to south from twenty-six to thirty-four miles, and twenty-three to thirty from west to east. It contains, by the lowest computation, 832 square miles, or 532,480 English acres, without including portions of the parishes of Lundie, Cupar, and Alyth, the greater part of which belongs to the county of Perth.

More than a third of its area is occupied by the Grampians, here called the Binchinnin Hills, on which it meets the Braes of Mar in Aberdeenshire. The surface of this northern division of the county, or the Braes of Angus, with the exception of the mountains at the head of Glen Clova, is not in general so bold and abrupt as many other alpine districts of Scotland; the hills are for the most part rounded, and rather tame, and covered with a thin coat of moorish soil, carrying stunted heath. Catlaw, the highest, is 2264 feet above the level of the sea. There are several considerable valleys in this district, the principal of which are Glen Isla, Glen Prosen, Clova, Lethnot, and Glen Esk, which are watered by streams that rise in the west and north, and commonly flow south-east, receiving innumerable torrents from the mountains in their progress. South from the Grampians, and parallel to them, is another but lower range, called the Siedlaw Hills, supposed to be a continuation of the Ochils; some of these hills are 1400 feet in height. Between these two grand divisions lies Strathmore, the Great Valley, as the name denotes in Gaelic, or, as it is commonly called, the How of Angus, extending about thirty-three miles in length, and from six to eight in breadth; a district beautifully diversified by gentle eminences, fertile fields, plantations, villages, and gentlemen's seats, very little of it being 200 feet above sea level. It was at one time proposed to carry a canal through this valley, which might be extended to Dumbarton, and thus connect the three great rivers of Scotland, the Clyde, the Forth, and the Tay; another from Arbroath to Forfar was also in contemplation; but neither of them has been carried into effect. The fourth, and remaining division, extends from the Siedlaw Hills to the German Ocean on the east, and the Frith of Tay on the south, and is, with a few exceptions, a rich and well-cultivated tract, varying in breadth from three to eight miles, and comprehending about a fourth part of the whole county.

The woods and plantations have been computed to extend to 35,000 acres, of which about 5000 consist of coppice and natural wood. Several of the Grampian glens are sprinkled with birches, oak, and hazels. The botany and zoology of the county were explored with great industry some years ago by Mr George Don of Forfar, who presented a very ample enumeration in both departments, in a paper subjoined to Mr Headrick's *Survey for the Board of Agriculture*.

The general colour of the soils is red, but often inclining to dark brown or black. In the Grampians the soil is often moorish, over whitish retentive clay, but loose and friable in the glens. Over the puddingstone or gravelstone rock in the lower grounds, it is sometimes thin, mossy, and encumbered with stones; and over the sandstone a tenacious clay occurs. The soil above whinstone is fertile, though sometimes shallow. In Strathmore it is often gravelly, in other parts a dead sand. There is no great extent of moss; but what exists is of much value for fuel.

The mineralogy of a considerable portion of Forfarshire was examined by Colonel Imrie, who has given a minute description of it in a paper published in the sixth volume of the *Transactions of the Royal Society of Edinburgh.* In the Grampian district, towards the summit of the county, on the confines of Aberdeenshire, the prevailing rock is granite, some of it very beautiful, with topazes or rock-crystals in its cavities or fissures, known by the name of *cairngorums*, from a mountain of that name in Aberdeenshire; also micaceous schistus, and porphyry dykes of the latter in some places intersecting the former. Laminated talc or mica, called by the shepherds *sheep's siller*, from its silvery lustre, which is sometimes thickly studded with small garnets, is found in irregular veins, and siliceous spar in jutting or detached hills. Lead was wrought at Gilfianan, above the old castle of Innermark, in the upper part of the parish of Lochlee, and also at Ardoch, near Mill-den, on the Esk. At the former place, according to Edward, in his *Description of Angus*, published in 1678, it yielded one sixty-fourth part of silver; but both mines have long since been abandoned. Limestone in small quantities frequently occurs, and is wrought in several parts; there are also broad veins of slate, but which, it is said, does not come off in plates of sufficient size for use. In descending the Grampians to Strathmore, gravelstone prevails, and afterwards, on the lower grounds, sandstone. Clay marl is found both in Strathmore and the Siedlaw Hills, but is little used. Shell marl is in greater request, and abounds in different parts, particularly in the lochs of Kinordie, near the bottom of the Grampians, Lundie in the Siedlaw Hills, Logie in the parish of Kirriemuir, and Restennet near Forfar. These lochs have been drained and rendered of easy access. It is also found in the lochs of Forfar, Rescobie, and Balgavies, where it is raised by scoops, and conveyed to the shore in boats. The Siedlaw Hills are chiefly composed of sandstone of various colours, some of it susceptible of a high polish. Sandstone flags, which are much used instead of slate for covering roofs, are raised in great quantities on the hill of Balmashanner, and in the moor to the south of Forfar; but the most extensive range of these flags is in the parish of Carmylie, and along the southern declivity of the Siedlaw Hills. The principal lime-works are in the maritime division, at Hedderwick near Montrose, and at Boddin in the parish of Craig, upon the sea-shore. The only mineral springs are chalybeate, one of which is near Montrose, another to the west of Arbroath, two in the side of a rivulet about a mile farther west, and one in the north-west corner of Dumbarrow in the parish of Dunichen.

The heaviest rains are from the east and south-east, and the heaviest snows from the north and north-east. At Crescent, half a mile westward of Dundee, the quantity of rain that fell during six years, from 1790 to 1795 inclusive, varied from 22·27 to 34·12 inches; but at Belmont, in the centre of Strathmore, during the same years, it was from 31·45 to 39·55 inches. The mean height of the barometer at Belmont, during the first three of these years, was 29·60, and that of the thermometer 42°. At Crescent, the mean degree of cold during winter, for the whole period, was from $32\frac{1}{3}^\circ$ to $39\frac{2}{3}^\circ$, and of heat during summer, from $60\frac{1}{5}^\circ$ to 66°. The south-east wind blows at Crescent twenty-one, and the south-west one hundred and nine days annually; whereas at Belmont the former prevails eighty-five and the latter one hundred and thirty-eight days.

The principal lochs or lakes have been already mentioned as containing shell-marl. To these may be added Lochlee among the Grampians, from which the North Esk issues, and Lentrathan near their base. None of the streams are so considerable as to have the name of rivers, but are called waters. The *North Esk*, after leaving Lochlee, flows towards the east, and then the south-east, where it forms the boundary between this county and Kincardineshire, and falls into the sea about three miles north-east of Montrose, having received the Mark, the Tarf, the Westwater, and the Cruick in its course. The *South Esk* rises in the north-western part of the county, among the Grampian summits of Clova, and passing by Brechin, discharges itself into the basin of Montrose, five miles from the mouth of the North Esk, after being joined by the waters of Prosen, Carritty, and other mountain streams. Its general course is from north-west to south-east. *Isla*, the last stream of any note, has also its source in the Grampians, flowing from the summit of the glen which bears its name, in a direction from north to south, until, at Ruthven, it bends to the westward, and joins the Tay in Perthshire. Below the bridge of Craig it has cut a chasm, in some places more than a hundred feet in depth, through a barrier of porphyry and gravelstone rocks, where it forms cascades of singular beauty. The Dean, the Lunan, the Dighty, and a few others, are inconsiderable streams.

Much of the landed property of Forfarshire has changed its owners within the last century; and of the forty barons mentioned by Edward, in the work already referred to, the descendants of not more than a third of them now possess estates in it. It is in general divided into estates of a moderate size. In 1811 a large proportion were from L.100 to L.1000 a year, some from L.2000 to L.6000; but only one or perhaps two worth L.12,000 a year. About a third part of the county is now held under entail. The valued rent is L.171,239. 16s. 8d. Scots, which is divided amongst two hundred and sixty-six estates, three fourths of which are below L.500 Scots. The real rent of the lands in 1811 was L.260,196. 15s., which is less than 10s. an acre; and of the houses, L.64,108 sterling. There are more than sixty gentlemen's seats, some of them venerable for their extent and antiquity, such as the Castles of Glammis, Brechin, and Airly, the house of Panmure, and others, distinguished for elegance and the beauty of their situation. Amongst the latter, Kinnaird Castle, the seat of Sir James Carnegie, is the most magnificent.

Farms are of every size, but in general not large, the average size of such as are arable being from 100 to 250 acres. There is a greater number below than above 100 acres. According to the *Agricultural Survey*, the whole number of farms in 1808 was 3222, of which about the half were under L.20 of yearly rent, and only eighty-six above L.300. In the western division of the Grampian district, the arable land is still held in runrig or intermixed, and the mountains in common, either without leases, or on leases not exceeding nine years. Throughout the rest of the county the leases are commonly for nineteen or twenty-one years. The farm-houses lately erected in the lower parts of the county are in general convenient and comfortable, but in the Grampians they are still miserable huts, with walls of stone and turf alternately, five feet high, and covered with thatch fastened with ropes in the form of a hay rick. In some parts where stones are scarce, cottages and even small farm-houses are built with clay, wrought up and mixed with straw, but in general the cottages are built with stone and clay, with clay floors and thatched roofs, one of which may be constructed for about L.15. Their number has been much diminished of late.

The agriculture of Forfarshire is for the most part respectable, though modern improvements are not so general as in the Lothians and border counties of Scotland. Wheat, which, according to Pennant, was a rare crop in 1775, is now cultivated to a great extent upon almost every variety of soil, to the height of 800 feet above the level of the sea; also barley, and all the other farm crops common in Scotland. In reaping the corn crops there is a practice peculiar to this and one or two of the contiguous counties, called *threaving;* the reaper is paid for his work not by the acre or by day-wages, but according to the number of sheaves he cuts down, or by the *threave,* which contains twenty-four or twenty-eight sheaves, the girth of which is specified. The advantages of this practice are, that women and children, who cannot perform full labour, find employment, working in families, on different parts of a field; whilst the farmer gets his crops cut low and clean, from its being their interest to fill the sheaf with the thickest part of the straw, which is always that nearest the ground. The unmarried men-servants, instead of boarding in the farmer's own house, often live apart in a place called the *bothy,* where they cook their own victuals.

No great progress has been made here in the improvement of live stock. The *garron,* a small breed of horses, keeps its ground in the Grampians, where the number employed is much too considerable for the work they have to perform. The Lanarkshire or west-country breed is common in the lower districts. There is supposed to be more than 9000 horses of all kinds and ages in the county, which were valued in 1811 at L.220,270. The cattle in the cultivated parts, when fat, weigh from forty to sixty stones, and in some instances a great deal more; and many more are fattened than reared, the practice on the grazing lands being to purchase them from the counties of Kincardine, Aberdeen, and Moray, and after making them fat, or nearly so, to sell them for the markets in the south. They are accordingly of a variety of breeds. Many of the permanent or stationary stock are without horns, and seem to be allied to the Galloways. Oxen were formerly employed in labour; but they are now rarely used except in turning up soils overrun with broom and other shrubs. The permanent stock of cattle is said to be about 37,400, worth L.261,800. There are few flocks of sheep, except in the Grampians and the highest of the Siedlaw Hills, though almost every residing proprietor, and many of the farmers, keep a small number. The original breed is the small white or yellow-faced; but the Linton, or black-faced, is the most numerous. The number is computed at 60,000, and the value at L.42,000. A herd of fallow-deer is kept in the park at Panmure.

Forfarshire contains five royal burghs, with a number of villages and hamlets; and a pretty large proportion of its inhabitants are employed in manufactures and commerce. The royal burghs are, 1. Forfar, the county town; 2. Dundee; 3. Aberbrothick, or Arbroath; 4. Montrose; and 5. Brechin. To these may be added Kirriemuir, a considerable village; Cupar Angus, of which, however, only a small part is in this county, most of it being in Perthshire; Glammis, Douglastown, and Letham. In 1808, 11,269,867½ yards of linen were stamped for sale in the county, the value of which was nearly half a million sterling. About half as much more, which was not stamped, might be made for domestic use and private sale.

There are two customhouses in Forfarshire; one at Dundee, and another at Montrose. For an account of the Dundee shipping trade, see the article DUNDEE. That at Montrose, including Johnshaven and Gourdon, amounts to 108 vessels, about 11,000 tons.

The fisheries on the coast of this county have not been prosecuted with great success. The boats employed are generally small, requiring only four hands. For some years considerable quantities of herrings have been caught in the months of June, July, and August. But the river fisheries have become of great value since the plan was adopted, at the suggestion of the late Mr Dempster of Dunichen, of conveying fresh salmon to London packed in ice. Mr Headrick estimates the produce of six of these fisheries in 1810 at L.7450. The greatest salmon fisheries are in the Frith of Tay, and were carried on chiefly by stake-nets, a practice which was objected to by the proprietors higher up the river, and which has been since declared illegal *intra fauces terræ,* or within the estuary.

Many religious and military ruins are to be found in Forfarshire. Near the cathedral of Brechin is a curious round tower, of which, though such be common in Ireland, only two, it is said, have been observed in Britain; this, and another similar to it at Abernethy, in Perthshire. (See the article BRECHIN.) At Arbroath are the remains of an abbey, founded by William the Lion in 1178, and very richly endowed, where was held the parliament of Robert Bruce which addressed the celebrated remonstrance to the Pope, asserting the independence of the kingdom. A hill fort called *Cater-thun,* in the parish of Menmuir, north-west of Brechin, is worthy of notice. Pennant thinks it was one of the posts occupied by the Caledonians before their engagement with Agricola, at the foot of the Grampians.

The county of Forfar sends one member to Parliament; the burgh of Dundee one; and Inverbervie, Montrose, Arbroath, Brechin, and Forfar one, Montrose being the returning burgh. It contains fifty-three entire parishes, besides portions of three others, which belong to presbyteries that meet at Forfar, Dundee, Brechin, Meigle, and Arbroath, and which, with the presbytery of Fordun, compose the synod of Angus and Mearns. There is no assessment for the poor in the county.

See Edward's *Description of Angus,* reprinted in 1791, and Colonel Imrie's *Section of the Grampians,* already referred to; *Beauties of Scotland,* vol. iv.; Headrick's *General View of the Agriculture of Angus or Forfarshire; Memoirs of the Wernerian Society,* vol. ii.; *The General Report of Scotland;* and Playfair's *Description of Scotland,* vol. i.

The following are the returns of the population for the years ending 1811, 1821, and 1831.

YEAR.	HOUSES.			OCCUPATIONS.			PERSONS.		
	Inhabited.	By how many Families occupied.	Uninhabited.	Families chiefly employed in Agriculture.	Families chiefly employed in Trade, Manufactures, or Handicraft.	All other Families not comprised in the two preceding classes.	Males.	Females.	Total of Persons.

1821	16,812	26,718	576	5114	15,348	6256	52,071	61,359	113,430
1831	...	...	...	...	...	...	65,093	74,513	139,606

Forfar, a royal burgh of Scotland, and capital of the county of Forfar, is situated in the lowest part of the county, which declines to it on all sides, and has rather a pleasant appearance. The streets are by no means regular, but many of the houses are well built and neat; an improvement, however, which has taken place within the last few years. At the beginning of the present century its streets were chiefly composed of old thatched houses, and its church was in a state of decay. But the town is now ornamented with a handsome suit of county buildings, situated in a good street. A new church with a steeple has likewise been erected, and an Episcopal chapel was opened in 1823. Besides these places of worship, some sects of dissenters have meeting-houses here. Forfar being the seat of the county courts of the sheriff, possesses a number of public offices and legal practitioners. There is a parish school, and an academy, where the languages, mathematics, and geography are taught. It has also an excellent news-room and library. The chief trade of Forfar is the weaving of osnaburgs and coarse linens. From time immemorial however it has been celebrated for the manufacture of *brogues* or strong shoes, such as are fitted for the rugged soil of the Highlands, where they are principally used by the inhabitants.

Forfar is a royal burgh of unknown antiquity, the privileges of which were confirmed in 1669, in virtue of which it is governed by a provost, two bailies, and nineteen counsellors, who are elected annually. The revenue of the burgh may be averaged at L.1000. On the west side of the town there is a beautiful sheet of water, which, although considerably reduced by draining, is still about a mile in length by half a mile in breadth. In former times Forfar was protected by a castle, which stood on a mound to the north of the town. Its origin is uncertain, but it is believed to have been the place where the first parliament of Malcolm Ceanmore assembled, after the destruction of Macbeth. The site of this ancient fortress is now marked by the town cross, which was removed by the magistrates some years ago, for the purpose of pointing out where the royal residence had been. Forfar has shared in the general advancement of population, trade, and agricultural improvement, and it is now one of the most comfortable little towns in the county. It lies fourteen miles north from Dundee, and fifty-six from Edinburgh. In 1821 the population, including the parish, amounted to 5897, and in 1831 to 7944.

FORFEITURE originally signifies a transgression or offence against some penal law. The word is formed from the base Latin *forisfactura*, whence *forfaitura* and *forfaictura*, and the French *forfait*. *Forisfactura* comes from *forisfacere*, which, according to Isidore, signifies to hurt or offend, *facere contra rationem*; and is not improbably derived from *foris*, out, and *facere*, to do, an action out of rule, or contrary to the rules. Borel thinks *forfait* is derived from the using of force or violence; and Lobineau, in his glossary, supposes *forisfacta* properly to signify a mulct or amend, not a *forfeit*, which latter he derives from the Bas-Breton, *forfed*, a penalty. But with us it is now more frequently used for the effect of such transgression, as the losing some right, privilege, estate, honour, office, or effects, in consequence thereof, than for the transgression itself. Forfeiture differs from confiscation in this, that the former is more general; whilst confiscation is particularly applied to such things as become forfeited to the king's exchequer; and goods confiscated are said to be such as nobody claims. See Treason.

FORFEX, in Roman antiquity, was a method of drawing up an army in the form of a pair of sheers, and intended to receive the *cuneus* or wedge, if the enemy should make use of that formation.

FORFICULA, the Earwig, a genus of insects belonging to the order of coleoptera. See Entomology.

FORGE properly signifies a small furnace, in which smiths and other artificers of iron, steel, or other metals, heat these metals red hot, in order to soften them and render them more malleable and manageable on the anvil.

An ordinary forge is nothing but a pair of bellows, the nozzle of which is directed upon a smooth area, on which coals are placed. The nozzle of a pair of bellows may also be directed to the bottom of any furnace, to excite the combustion of the coals placed there, by which a kind of forge is formed. In laboratories there is generally a small furnace consisting of one cylindrical piece, open at top, which has at its lower side a hole for receiving the nozzle of a double bellows. This kind of forge furnace is very convenient for fusions, as the operation is quickly performed, with a small expenditure of fuel. In its lower part, two inches above the hole for receiving the nozzle of the bellows, may be placed an iron plate of the same diameter, supported upon two horizontal bars, and pierced near its circumference with four holes diametrically opposite to each other. By this disposition, the wind of the bellows, pushed forcibly under this plate, enters at these four holes; and thus the heat of the fire is equably distributed, and the crucible in the furnace is surrounded by it. This contrivance is used in the forge-furnaces for smelting copper; with this difference only, that these furnaces are square, which, however, is a matter of little consequence.

As the wind of bellows strongly and rapidly excites the action of the fire, a forge is very convenient when a great heat is to be applied quickly; but it is not suitable when the heat is to be gradually increased.

Forge is also used for a large furnace, in which iron ore, taken out of the mine, is melted down; or it is more properly applied to another kind of furnace, in which the iron-ore, melted down and separated in a former furnace, and then cast into sows and pigs, is heated and fused over again, and beaten afterwards with large hammers, and thus rendered softer, purer, more ductile, and better fitted for use. See Furnace.

FORGERY (from the French *forger*, signifying *accudere, fabricare*, to beat on an anvil, forge, or form), may be defined at common law to be the fraudulent making or alteration of a writing, to the prejudice of another man's right; or it is the crime of imitating the subscription of another, adhibiting it to a deed, and putting that deed to use by acting under it, receiving property in virtue of it, founding on it as a title to sue or to defend, or transferring it to another. In considering forgery, it is necessary to attend, first, to the mode of proof by which the crime is established; and, secondly, to the punishment which is inflicted on the perpetrator thereof.

The proof of forgery is either direct or indirect. The direct proof consists in the examination of the writer of the deed, and of the witnesses who sign the deed and attest the subscription. As the subscription of witnesses is an attestation to which the law gives effect to the extent of receiving it on their death as evidence of the regularity of the deed, and as weight is given to the subscription of a witness, even where he does not recollect having adhibited it; so, to cut down a deed regularly attested, the instrumentary witnesses, as they are called in Scotland, must be brought to swear to circumstances of sufficient force to invalidate the evidence given by their subscriptions; a species of proof which the law does not and indeed cannot reject. The indirect mode of proof consists in an investigation of all the circumstances from which it may be inferred that the person by whom a deed is said to have been executed actually did not subscribe; as, for instance, an error in the date, an *alibi*, the stamp, the contexture of or date impressed upon the paper, or a *comparatio literarum*. The comparison of the handwriting is made with genuine subscriptions of the same date as that alleged to have been forged; and where the real subscriptions differ materially from the one founded on, the forgery of the latter may be pronounced on with a considerable degree of certainty. The indirect mode of proof, however, is not resorted to where the direct mode is practicable.

Until recently the punishment of forgery was not expressly laid down by statute; but by the common law and practice of the country, conviction was usually followed by a capital punishment in all cases of gross forgery; whilst those of less moment, as forgeries of executions, or where the evidence was not in every respect conclusive, were commonly visited with what in Scotland is denominated an arbitrary punishment, that is, with imprisonment or transportation. Latterly, however, the severity of the law in this particular has been considerably mitigated, and the punishment of death restricted to those cases of forgery which are not only the most aggravated in their own nature, but at the same time calculated to prove most extensively injurious to the interests and well-being of society. By the 2d and 3d William IV. c. 123, entitled an "act for abolishing the punishment of death in certain cases of forgery," it is enacted that where any person shall thereafter be convicted of any offence whatsoever for which the 1st William IV. c. 66 (entitled an "act for reducing into one all such forgeries as shall hereafter be punished with death, and for otherwise amending the laws relative to forgery") enjoins or authorizes the infliction of the punishment of death, or for any offence which shall consist wholly or in part of forging or altering any writing, instrument, matter, or thing whatsoever, or of offering, uttering, or disposing of any writing, instrument, matter, or thing whatsoever, knowing the same to be forged or altered, or of falsely personating another, such offender shall not suffer death, or have sentence of death awarded against him, but shall be transported beyond seas for the term of such offender's life. But it is at the same time specially provided that nothing in this act shall be construed to extend to the forging or altering, offering, uttering or disposing of, knowing the same to be forged or altered, any will, codicil, or testamentary writing, with intent to defraud any body corporate or person whatsoever, or of forging or altering, or of uttering knowing the same to be forged, any power of attorney or other authority to transfer any share or interest in any stock, annuity, or other fund, transferable at the Bank of England or South-Sea House, or Bank of Ireland, or to receive any dividend payable in respect of such share or interest, with intent to defraud any body corporate or person whatsoever, or of procuring, aiding, or assisting in the commission of such offences, for all which offences the punishment of death is to continue the same as if this act had not been passed. And further, by 2d and 3d William IV. c. 44, it is enacted that persons punishable with transportation for life under the foregoing act shall be liable, previously to their being transported, in case the court before which they are convicted shall think fit, to be imprisoned, with or without hard labour, in the common gaol or house of correction, or to be confined in the penitentiary for any term not exceeding four years nor less than one. Such is now the state of the law on this subject. As it formerly stood its excessive severity had rendered it to a certain extent inoperative; for as the natural feelings of mankind revolt at the indiscriminate sacrifice of human life for offences of a secondary description, judges and juries had tacitly combined to evade giving it effect in the less aggravated class of cases, and thus to reconcile with public opinion the practical administration of justice in this particular. But as all such evasions, however humane in their spirit, are pregnant with manifold evils, it is to be hoped that the mitigation which has taken place will augment the efficacy of the law by increasing the certainty of the punishment it awards, and that hence will result a diminution in the number of offences of this kind, which the excessive but irregular severity of the law, as it formerly stood, had failed to produce. (A.)

FORGING, in smithery, the beating or hammering iron upon an anvil, after having first made it red hot in the forge, in order to extend it into various forms, and fashion it into various works.

There are two ways of forging and hammering iron. The first is by the force of the hand, in which there are usually several persons employed, one turning the iron and likewise hammering, and the rest only hammering. The other way is by the force of a water-mill, which raises and works several huge hammers beyond the force of man, under which the workmen place large lumps or pieces of iron, which are sustained at one end by the anvils, and at the other by iron chains fastened to the ceiling of the forge. This last way of forging is only used in the largest works, as anchors for ships, which usually weigh several thousand pounds. For the lighter works a single man is sufficient to hold, heat, and turn with one hand, whilst he hammers with the other.

FORISFAMILIATION, in *Law*. When a child, upon receiving a portion from his father, or otherwise, renounces his legal title to any further share of his father's succession, he is said to be *forisfamiliated*.

FORK, a well-known instrument, consisting of a handle and blade, divided at the end into two or more points or prongs. The *table-fork* did not come into use in England till the reign of James I., as we learn from a remarkable passage in Coryat. The reader will probably smile at the solemn manner in which this important discovery or innovation is related: "Here I will mention a thing that might have been spoken of before in discourse of the first Italian townes. I observed a custom in all those Italian cities and townes through the which I passed, that is not used in any other country that I saw in my travels, neither do I thinke that any other nation of Christendome doth use it, but only Italy. The Italians, and also most strangers that are commorant in Italy, doe always at their meals use a little forke when they eat their meate; for while with their knife, which they hold in one hand, they cut the meate out of the dish, they fasten the forke, which they hold in the other hand, upon the same dish, so that whatsoever he be that sitting in the company of any others at meale shall unadvisedly touch the dish of meat with his fingers from which all the table doe cut, he will give occasion of offence unto the company as having transgressed the lawes of good manners, insomuch that for his error he shall be at least browbeaten, if not reprehended in wordes. This form of feeding I understand is generally used in all parts of Italy, their forkes for the most part being made of yronn, steele, and some of silver, but those are used only by gentlemen. The reason of this their curiosity is, because the Italian cannot by any means indure to have his dish touched with fingers, seeing all men's fingers are not alike cleane. Hereupon I myself thought good to imitate the Italian fashion by this forked cutting of meate, not only while I was in Italy, but also in Germany, and often times in England since I came home: being once quipped for that frequently using my forke, by a certain learned gentleman, a familiar friend of mine, Mr Lawrence Whitaker, who in his merry humour doubted not to call me a table *furcifer*, only for using a forke at feeding, but for no other cause."

FORLI, one of the delegations of the papal dominion, in Italy, 1232 square miles in extent. It contains six cities, nineteen market-towns, and a great number of villages, with 150,930 inhabitants. It extends from the foot of the Appennines to the sea-shore, and is watered by several streams descending from those mountains, one of which, but not accurately ascertained, is the celebrated Rubicon. On the sea-shore are many morasses which generate malaria, but the remainder of the province is tolerably healthy, and highly fertile. The chief city, of the same name, is situated on the Via Æmilia, between the rivers Mentone and Ronco. It contains nine parish churches, sixteen monasteries, and seven nunneries. The population is 15,520. It has fabrics of silks, refineries for salt and for sulphur, linen weaving, and wax bleaching. Long. 12. 18. 5. E. Lat. 44. 13. 25. N.

FORLIMPOPOLI, an open city of the delegation Forli, in the papal dominions, in Italy, which, united with Bertinoro, forms a bishopric. It contains 5806 inhabitants.

FORLORN HOPE, in the military art, signifies men detached from several regiments, or otherwise appointed, to make the first attack in day of battle; or, at a siege, to storm the counterscarp, mount the breach, or the like. They are so called from the great danger to which they are unavoidably exposed.

FORM, in *Physics*, denotes the manner of being peculiar to each body; or that which constitutes it such a particular body, and distinguishes it from every other. But Mr Harris uses the term *form* in another sense, as an efficient animating principle; to which he supposes Ovid to refer in the first lines of his Metamorphoses.

> *In nova fert animus mutatas dicere* formas,
> *Corpora.*

These animating forms are not of themselves objects either of the ear or of the eye; but their nature or character is understood in this, that were they never to exert their proper energies on their proper subjects, the marble on which the sculptor exercises his art would remain for ever shapeless, and the harp from which the harper calls forth sounds would remain for ever silent.

Substantial forms seem to have been first broached by the followers of Aristotle, who thought matter, under different modes or modifications, not sufficient to constitute different bodies, but that something substantial was necessary to set them at a greater distance, and thus introduced substantial forms, on the footing of souls, which specify and distinguish animals. What led to this erroneous notion were the circumstances of life and death. For observing that, as soon as the soul had departed out of a man, all motion, respiration, nutrition, and other animal functions, immediately ceased, they concluded that these functions depended on the soul, and consequently that the soul was the form of the animal body, or that which constituted it such; indeed nobody doubted that the soul was a substance independent of matter; and hence it was concluded that the forms of other bodies were to be equally substantial. But to this it is answered, that though the soul be that by which man is man, and consequently the form of the human body as human, yet it does not follow that it is properly the form of this body of ours, as it is a body, or of the several parts thereof, considered as distinct from one another. For those several parts have their proper forms so closely connected with their matter, that it remains inseparable therefrom long after the soul has quitted the body; thus flesh has the form of flesh, bone of bone, and so forth, long after the soul is removed, as well as before. The truth is, the body does not become incapable of performing its accustomed functions because the soul has deserted it; but the soul takes its leave because the body is no longer in a condition to perform its functions.

The ancient and modern corpuscular philosophers, therefore, with the Cartesians, exclude the notion of substantial forms, and show, by many arguments, that the form is only the *modus* or manner of the body in which it is inherent. And as there are only three primary modes of matter, figure, rest, or motion, with two others arising therefrom, magnitude and situation, the form of all bodies they hold to consist in these modes, and suppose the variations which they are capable of sufficient to present all the variety observable in bodies.

Forms are usually distinguished into *essential* and *accidental.* Though the five modes above mentioned, generally taken, be adventitious, yet to this or that body, as to fire or water, they are *essential.* Thus it is *accidental* to iron to have this or that magnitude, figure, or situation, since it might exist in different ones; yet to a knife or hammer, the figure, magnitude, and position of parts, which constitute it a hammer or knife, are essential, and they cannot exist or be conceived without these. Hence it is inferred, that though there be no substantial, yet there are essential forms, by which the several species of bodies become what they are, and are distinguished from all others. *Accidental* forms are those really inherent in bodies, but in such manner as that the body may exist in all its perfection without them; such as whiteness in a wall, heat in water, a figure of a man in wax, and so on.

Form, in carpentry, is used to denote the long seats or benches in the choirs of churches or in schools, for the priests, prebends, religious persons, or scholars, to sit on. Du Cange supposes the name to be derived from this, that the backs of the seats were anciently enriched with figures of painting and sculpture, called in Latin *formæ et typi.* In the life of St William of Roschild, we meet with *forma* as signifying a seat for an ecclesiastic, or religious person, in a choir; and in that of St Lupicin, we find *formula* used in the same sense. In the rule of the monastery of St Cæsarea, the man who presides over the choir is called the occupant of the first form or seat.

FORMALITY, as defined in the schools, is any manner in which a thing is conceived; or a manner in any object, importing a relation to the understanding by which it may be distinguished from another object. Thus animality and rationality are formalities. The Scotists made great use of formalities, in opposition to the virtualities of the Thomists.

Formalities, in matters of law, are frequently used for the formulas themselves, or the rules prescribed for judicial procedure. In contracts of strict law all the formalities must be strictly observed, as an omission of the least may ruin the whole convention.

FORMAN, Andrew, archbishop of St Andrews, Earl of Pittenweem, and of Cottingham in England, one of the lords of the regency appointed by the states during the minority of King James V. of Scotland, legate *a latere*, primate of all the kingdom of Scotland, and archbishop of Bourges in France, was descended from the family of the Formans of Hutton in the county of Berwick, and is considered as having been one of the best statesmen of the age in which he lived. He was employed in 1501, along with Robert Blackader, archbishop of Glasgow, and Patrick earl of Bothwell, to negotiate a match between James IV. of Scotland, and Margaret eldest daughter of Henry VII. of England, which next year was ratified by the Scottish ambassadors. He was afterwards frequently employed as Scottish ambassador to Rome, England, and France, upon the most important occasions. In 1514 he was translated from the see of Moray, to which he had been appointed in 1502, to that of St Andrews. During the time he possessed the former, he was employed as mediator between Pope Julius II. and Louis XII. of France, who were at that time at variance; and he happily succeeded in conciliating the difference. Having taken leave of the pope, he on his return home passed through France, where he was kindly received by the king and queen, who bestowed upon him the bishopric of Bourges in France, which brought him annually 400 tuns of wine, 10,000 francs of gold, and other smaller matters. Besides this, he was most liberally rewarded by Pope Julius, who promoted him to the archbishopric of St Andrews, as has been already mentioned, conferred on him the two rich abbeys of Dunfermline and Aberbrothick, and made him his legate *a latere*. At that time, however, there were two other candidates for the archiepiscopal see. The learned Gavin Douglas, bishop of Dunkeld, having been nominated by the queen, had actually taken possession; but John Hepburn, a bold and factious man, having been preferred by the monks, drove out the officers of Gavin Douglas, and placed a strong garrison in the castle. And so great was the power of this man, that when Forman was nominated by the pope, no person could be found to proclaim the bulls for his election. At last Lord Home, at that time the most powerful nobleman in Scotland, was induced, by large promises, besides some considerable gifts, amongst which was the donation of the abbacy of Coldingham to his youngest brother David, to undertake the task. It was executed at Edinburgh and at St Andrews, to which places Lord Home's brother proceeded with 10,000 men; though the doing of it, contrary to Forman's inclination, proved a source of much trouble to that nobleman afterwards. The quarrel between Hepburn and Forman, however, was at last terminated by the latter surrendering the bishopric of Moray, as well as some years' revenue of the archbishopric itself, and paying Hepburn three thousand French crowns annually out of his ecclesiastical revenues. On the appointment of the Duke of Albany to the regency, Hepburn endeavoured to undermine the primate's credit with that nobleman, by representing him as one who had in a manner collected all the money in the country, and who consequently might endanger the tranquillity of the kingdom. These insinuations, however, were but little regarded by the regent; and Forman had the good fortune afterwards to compose a difference between him and the nobility, which was likely to be attended with bloodshed. In 1517 the archbishop was appointed by the states one of the lords of the regency, on the occasion of the Duke of Albany's going to France. His embassy to Pope Julius II. has been already mentioned. In Mackenzie's Lives we are informed, that in the collection of the Letters of the Scottish Kings from the year 1505 till the year 1626, in the Advocates' Library, there is a letter from the pope to King James IV., in which he not only commends Forman highly, but likewise promises that at the first creation of cardinals he should be made one. This letter is dated the 6th of May 1511; but the pope died before he had an opportunity of performing his promise. In the same collection there is a letter from the Duke of Albany to Leo X., successor of Julius, in which he urges the pope to advance Forman to the dignity of a cardinal, promised him by his predecessor, and to continue him as legate *a latere*. Archbishop Forman died in the year 1521, and was buried at Dunfermline. Dempster says that he wrote a book against Luther, a book concerning the Stoical philosophy, and a collection out of the Decretals.

FORMATION, in *Philosophy*, an act by which something is formed or produced.

FORMATION, in *Geology*. See MINERALOGY.

FORMATION, in *Grammar*, signifies the manner of forming one word from another. Thus *accountantship* is formed from *accountant*, and this last from *account*.

FORMEDON, in *Law* (*breve de forma donationis*), a writ that lies for a person who has a right to lands or tenements, by virtue of any entail, arising from the statute of Westminster.

FORMENTERA, one of the Balearic Islands, in the Mediterranean Sea, belonging to the crown of Spain. It lies to the south of Iviça, is twelve miles in length, in some parts eight miles, and in others, from great indentations, not more than half a mile in breadth. Its name is derived from the abundant crops of wheat which are produced on the western part of the island, whilst the eastern part is almost wholly covered with thick woods. There is no town on the island; but it is peopled by 1500 inhabitants, who live in villages or sequestered cottages. It is separated from Iviça by a strait two miles across, in the middle of which is the small island Espalmado.

FORMICA, the ANT. See ENTOMOLOGY.

FORMING is used for the act of giving being or birth to any thing. The word is also simply used for giving figure to any thing. The potter forms his vessels as he pleases. Geometry teaches how to form all kinds of figures.

FORMING *of a Siege*, is the making lines of circumvallation, to fortify the camp, and disposing things for the attack of a place in form.

FORMING *the Line*, is drawing up infantry, cavalry, and artillery, in order of battle.

FORMING is also used in grammar, in speaking of certain tenses of verbs, which are made from others by a change of certain letters. The present tense is formed from the infinitive. Compound and derivative words, also, and even all that have any etymology, are said to be formed.

FORMOSA, a large island in the Eastern Seas, more properly called Tywan. It is about 180 miles in length by 50 in breadth, is distant 100 miles from the south-east coast of China, and lies between the twenty-third and twenty-sixth degrees of north latitude. The Dutch at an early period established a settlement on this island; and it was long subject to their authority. In 1625 the viceroy of the Philippine Islands sent an expedition against Formosa, with a view to expel the Dutch, and to propagate the Roman Catholic religion in the island. But after erecting fortifications, the Spaniards abandoned the island. About the middle of the seventeenth century it afforded a retreat to 20,000 or 30,000 Chinese, from the fury of the Tartar conquest. These refugees were, according to the usual habits of the Chinese, very industrious; and they carried on a lucrative trade with their countrymen in China, which proved the source of an abundant revenue to the Dutch government. A profitable trade was also carried on by the Dutch with Japan. In 1653 a conspiracy of the Chinese inhabitants against the Dutch was discovered and suppressed; and soon after this, Coxinga, the governor of the maritime Chinese province of Tehichiang, applied for permission to retire to the island, which was refused by the Dutch governor; on which he fitted out an expedition consisting of 600 vessels, and made himself master of the town of Formosa and the adjacent country, and afterwards besieged and took Fort Zealand, when the Dutch were all allowed to embark and leave the island. The loss of this convenient station and entrepôt of trade was severely felt by their East India Company. Coxinga afterwards engaged in a war with the Chinese and the Dutch, in which he was defeated and slain. But they were not able to obtain possession of the island, which was bravely defended by the posterity of Coxinga; and it was not till the year 1683 that the island was voluntarily surrendered by the reigning prince to the emperor of China, and it has ever since remained in possession of the Chinese. In 1676 the English had a factory at Formosa, the chief object of which was to carry on a trade with Japan. In 1805, through the weakness of the Chinese government, the Ladrone pirates had acquired possession of a great part of the south-west coast of Formosa.

FORMULA, or FORMULARY, a rule or model, or certain terms prescribed or decreed by authority, for the form and manner of an act, instrument, proceeding, or the like.

Forres.

Formula, in *Ecclesiastical History* and *Theology*, signifies a profession of faith.

Formula, in *Medicine*, imports the constitution of medicines, either simple or compound, both with respect to their prescription and their consistence.

Formula, a theorem or general rule or expression, for solving certain particular cases of some problem; so $\frac{1}{2}s + \frac{1}{2}d$ is a general formula for the greater of two quantities whose sum is s, and difference d; and $\frac{1}{2}s - \frac{1}{2}d$ is the formula or general value for the less quantity. Also $\sqrt{dx - x^2}$ is the formula or general value of the ordinate to a circle whose diameter is d and absciss x.

FORMULARY, a writing containing the form or formula of an oath, declaration, attestation, or abjuration, to be made on certain occasions. There are also formularies of devotion, of prayers, and the like. Liturgies are formularies of the public service in most churches.

FORNACALIA, or **Fornicalia**, in Roman antiquity, a festival instituted by Numa, in honour of Fornax, the goddess of ovens, in which certain cakes were made, and offered in sacrifice before the ovens.

FORNICATION (*fornicatio*, from the *fornices* in Rome, where the lewd women prostituted themselves for money), the act of incontinency between single persons. Upon this subject we find the following observations in Paley's *Moral and Political Philosophy*:—

"The Scriptures give no sanction to those austerities which have been since imposed upon the world under the name of Christ's religion, as the celibacy of the clergy, the praise of perpetual virginity, the *prohibitio concubitus cum gravida uxore*; but, with a just knowledge of, and regard to, the condition and interest of the human species, have provided in the marriage of one man with one woman an adequate gratification for the propensities of their nature, and have restrained them to that gratification.

"The avowed toleration, and in some countries the licensing, taxing, and regulating of public brothels, has appeared to the people an authorizing of fornication, and has contributed, with other causes, so far to vitiate the public opinion, that there is no practice of which the immorality is so little thought of or acknowledged, although there are few in which it can more plainly be made out. The legislators who have patronized receptacles of prostitution ought to have foreseen this effect, as well as considered, that whatever facilitates fornication, diminishes marriages. And as to the usual apology for this relaxed discipline, the danger of greater enormities if access to prostitutes were too strictly watched and prohibited, it will be time enough to look to that after the laws and the magistrates have done their utmost. The greatest vigilance of both will do more than oppose some bounds and some difficulties to this intercourse. And after all, these pretended fears are without foundation in experience. The men are in all respects the most virtuous in countries where the women are most chaste.

"If fornication be criminal, all those incentives which lead to it are accessaries to the crime; as lascivious conversation, whether expressed in obscene or disguised under modest phrases; also wanton songs, pictures, books, the writing, publishing, and circulating of which, whether out of frolic or for some pitiful profit, is productive of so extensive a mischief from so mean a temptation, that few crimes within the reach of private wickedness have more to answer for, or less to plead in their excuse."

FORNIX, in *Anatomy*, is a part of the *corpus callosum* in the brain, so called on account of a distant resemblance to the arch of an ancient vault when viewed in a particular manner.

FORQUALQUIER, an arrondissement of the department of the Lower Alps, in France, extending over 369 square miles. It is divided into six cantons and fifty-two communes, and contains 32,411 inhabitants. The capital is a town of the same name, situated on a plain through which the river Laye flows, and which yields wine, olive oil, and much silk. The latter is extensively spun there. It contains 2741 inhabitants. Long. 5. 46. E. Lat. 43. 58. N.

FORRES, a royal burgh of Scotland, in the county of Moray. It stands on a rising ground, at the distance of three miles from the mouth of the Findhorn, and is neat and well built. The trade carried on here is not very extensive; amongst other articles, straw plait for bonnets is manufactured. In this town there is a fine stone building, called Anderson's Institution, which was founded in 1824. Here the youth of Forres, Rafford, and Kinloss, are taught the classics, mathematics, natural philosophy, and other branches of education. Besides this academy there are several private schools in Forres; and a news-room, a subscription library, and various friendly societies. The places of worship are the parish church, a meeting-house of the United Secession church, and another of the Independents. At the western extremity of the town is an eminence on which stood the castle of Forres. This is an object of curiosity; for here Duffus, one of the early kings of Scotland, was killed by Donwald, governor of the castle. The river Findhorn runs immediately behind the eminence. At this place a very handsome bridge was swept away by the great flood of August 1829, which will be noticed in the article Morayshire. Forres is noted for the possession of one of the most remarkable ancient stone obelisks to be found in Britain. It is thus described by Mr Cordiner, in a letter to Mr Pennant: "In the first division, underneath the Gothic ornaments at the top, are nine horses with their riders marching forth in order. In the next is a line of warriors on foot, brandishing their weapons, and appear to be shouting for the battle. The import of the attitudes in the third division is very dubious, their expression indefinite. The figures which form a square in the middle of the column are pretty complex, but distinct; four serjeants with their halberts guard a canopy, under which are placed several human heads which have belonged to the dead bodies piled up at the left of the division; one appears in the character of executioner severing the head from another body; behind him are three trumpeters sounding their trumpets, and before him two pair of combatants fighting with sword and target. A troop of horse next appears, put to flight by infantry, whose first line have bows and arrows, the three following swords and targets. In the lowermost division now visible, the horses seem to be seized by the victorious party, their riders beheaded, and the head of their chief hung in chains or placed in a frame; the others being thrown together beside the dead bodies under an arched cover. The greatest part of the other side of the obelisk, occupied by a sumptuous cross, is covered over with an uniform figure, elaborately raised, and interwoven with great mathematical exactness. Under the cross are two august personages, with some attendants, much obliterated, but evidently in an attitude of reconciliation; and if the monument was erected in memory of the peace concluded between Malcolm and Canute, upon the final retreat of the Danes, these large figures may represent the reconciled monarchs. On the edge below the fretwork are some rows of figures joined hand in hand, which may also imply the new degree of confidence and security which took place, after the feuds were composed, which were characterized on the front of the pillar. But to whatever particular transaction it may allude, it can hardly be imagined that, in so early an age of the arts in Scotland as it must have been raised, so elaborate a performance would have been undertaken but in consequence of an event of the most general importance; it is therefore surprising that no distincter traditions of it arrived at the era when letters were known. The height of this monument (called *King Sueno's Stone*) above the ground is twenty-three feet, besides twelve or fifteen feet under ground. Its breadth is three feet ten inches by one foot three inches in thickness."

FORSTER, John Reinhold, a celebrated naturalist and geographer, and an accomplished scholar and linguist, was born on the 22d October 1729, at Dirschau, in Polish Prussia, where his father was burgomaster or mayor. His family was of English descent, and had quitted Great Britain in the time of Charles I.

At the age of fourteen he was placed for a year at the public school of Marienwerder, and was afterwards admitted into the gymnasium of Joachimsthal at Berlin. Among his schoolfellows was Pallas, who became so well known for his various researches in natural history, with several others who distinguished themselves in literature and science. He applied himself with diligence to the study of the ancient and modern languages, and in particular of the oriental languages, as connected with divinity. He continued the same pursuits at the university of Halle, which he entered in 1748. After three years, having completed his theological studies, he resided for two years more at Dantzick, preaching as a candidate. In 1753 he obtained a small benefice at the neighbouring town of Nassenhuben, and the next year he married his cousin Elizabeth Nikolai; but he still found leisure to improve himself in natural philosophy, geography, and the mathematics. His increasing family having become too expensive for his income, he accepted the proposals of the Russian consul at Dantzick, and agreed to superintend the establishment of the new colonies at Saratof on the Volga. The consul received the thanks of the reigning favourite, Count Orlof, for his judicious selection of a person so well qualified; but our adventurer was not satisfied with his success in the undertaking, and, in 1766, he resolved, somewhat suddenly, to try his fortune in England, whither he proceeded well recommended, but with exhausted finances. Soon afterwards, however, he received a gratuity of 100 guineas from the Russian government, and he obtained some remuneration from the booksellers for his translations from the German and the Swedish. He declined a proposal of Lord Baltimore, who offered him the management of his large estates in America, preferring the appointment of a teacher of modern languages and natural history in the dissenting academy of Warrington, where he found a more interesting society than would have been attainable in any part of the New World. He was not, however, very popular as an instructor; and he was soon after this engaged to accompany Mr Dalrymple, who was going out as governor of Balambanjan, near Borneo; but the plan was never executed. In 1772 he was appointed naturalist to the expedition under the command of Captain Cook in his second voyage of circumnavigation; and he took with him his son George, then seventeen years old. For this undertaking Forster was abundantly qualified as a man of science and an accurate observer, though his temper and conduct were not always such as to make him agreeable to his shipmates, nor was he uniformly considerate and humane in his intercourse with the uncivilized inhabitants of the countries which he explored. After the return of the expedition, there were repeated discussions and disputes respecting Forster's share in the intended publication of the narrative of the voyage. Two thousand pounds, which had been granted by government for the plates of the work, were to have been equally divided between Cook and Forster for this purpose; but Forster's performance of his part of the undertaking was disapproved, and he was deprived of the advantage which he expected to have derived from the plates. It is possible that he may have expressed himself incautiously respecting the conduct of the expedition; perhaps also he may have been thought deficient in accuracy of idiom; for he was more fluent than correct or elegant in the various languages which he was in the habit of speaking and writing. He was, however, supposed to be concerned in the account of the voyage which was published by his son; and this participation was considered by his opponents, and even by many of his friends, as an infringement of the conditions of his engagement; besides that many offensive remarks and a few inaccuracies were introduced into the work, some of which were afterwards candidly admitted and corrected by his son. All these circumstances made Forster's residence in England by no means agreeable, and his pecuniary embarrassments became so pressing that he was at one time in confinement for debt. He was, however, set at liberty in 1780, by the munificence of the king of Prussia, who furnished him with the means of satisfying his creditors, and established him at Halle, as professor of natural history, and inspector of the botanical garden. The year after he took the degree of doctor of physic in the university. He was not always on the most cordial terms with his academical colleagues, and he was too fond of accusing them in his reports to his superiors. His circumstances were also much embarrassed by his unfortunate propensity to play, which absorbed the whole earnings of his labour. He, however, considered the eighteen years that he spent at Halle as the happiest of his life. He was much afflicted in his old age by the premature death of his two sons; indeed his health seemed to be impaired by his grief, and he died on the 9th December 1798. Professor Kurt Sprengel has written an account of his life, containing a just encomium on his various talents and acquirements, though somewhat too flattering with regard to his moral character. He appears to have been master of seventeen different languages; and he was as extensively acquainted with things as with words, being as much indebted for his various knowledge to his industrious and accurate observation of nature, as to his great reading and his profound learning. He was long intimate with Buffon, and greatly admired his writings; and he was in constant correspondence with Linnæus and his son, the latter of whom gave the name of *Forstera* to a new genus of plants, in compliment to the two botanists who had discovered it in New Zealand. In conversation he was witty, but frequently too satirical; and his unguarded sallies created him many enemies. He became a fellow of the Society of Antiquaries soon after his arrival in England; in February 1772 he was elected a fellow of the Royal Society; and in 1775, upon his return from the South Seas, the university of Oxford conferred on him the honorary diploma of a doctor of laws. His principal publications are these:

1. *Specimen Historiæ Naturalis Volgensis, Phil. Trans.* 1767, p. 312, containing a geographical description of the country about Saratof, and an ample enumeration of its various productions. 2. *An Introduction to Mineralogy, or an accurate Classification of Fossils and Minerals*, 8vo, London, 1768; with a *Translation of* Lehman's *Halotechnia*, intended principally as a text-book for a course of lectures delivered at Warrington. 3. *A Catalogue of British Insects*, 8vo, Warrington, 1770. 4. *A Translation of* Kalm's *Travels into North America*, 3 vols. 8vo, Warrington and London, 1770, 1771. 5. Osbeck's *Voyage to China and the East Indies, translated from the German; with a Faunula and Flora Sinensis*, 2 vols. 8vo, London, 1771. 6. *A Translation of* Bossu's *Travels in Louisiana, with Notes, and a Systematic Catalogue of all the known Plants of English North America; together with an Abstract of* Löfling's *Travels*, 2 vols. 8vo, London, 1771. 7. *Novæ Species Insectorum*, Centuria 1, 8vo, London, 1771; consisting chiefly of English insects, together with a few foreign

ones, arranged according to the Linnæan system, with the adoption of two genera from Geoffroy. 8. *An Account of the management of Carp in Polish Prussia, Ph. Tr.* 1771, p. 310, in a letter to the Honourable Daines Barrington. It appears that the carp is a kind of staple commodity of that country. 9. *An Easy Method of Assaying and Classing Mineral Substances, with a Translation of* Schecle's *Experiments on Sparry Fluor, from the Memoirs of the Swedish Academy*, 8vo, London, 1772. 10. *Translation of* Bougainville's *Voyage*, 4to, London, 1772. 11. *Epistolæ ad* J. D. Michaelis, 4to, Göttingen, 1772, containing remarks on this author's *Spicilegium Geographiæ Exteræ*. 12. *An Account of the Roots used by the Indians in the neighbourhood of Hudson's Bay to dye Porcupines' Quills, Phil. Tr.* 1772, p. 54; the Galium tinctorium and Helleborus trifolius. 13. *An Account of several Quadrupeds from Hudson's Bay, Phil. Tr.* 1772, p. 370; describing a collection of specimens sent to the Royal Society from the Factory at Hudson's Bay. 14. *An Account of the Birds sent from Hudson's Bay,* p. 382. 15. *An Account of some Curious Fishes sent from Hudson's Bay, Phil. Tr.* 1773, p. 149, addressed to T. Pennant, Esq. These papers were published during the author's absence with Captain Cook. 16. 17. He translated Grainger's *Travels* and Riedesel's *Travels*, in conjunction with his son George. 18. He made a *Catalogue of the Animals and Plants represented in Catesby's Carolina, with the Linnæan names.* 19. *Characteres generum plantarum, quas in itinere ad insulas maris australis collegerunt* J. R. et G. Forster, folio, London, 1776, containing descriptions and figures of 75 new genera. 20. *Liber singularis, de Bysso antiquorum, quo ex Ægyptiaca lingua res vestiaria antiquorum, imprimis in sacro codice occurrens explicatur*, 8vo, London, 1776. The object of this essay is to prove that the *byssus* of the ancients was cotton, and not fine linen, in which the author succeeds without difficulty; and he states, that all the cloths enveloping the mummies that he has been able to examine are uniformly cotton. In his Egyptian etymologies he is learned and ingenious, but, like almost all other Egyptian etymologists, extremely precipitate. 21. *Observations made during a Voyage Round the World, on Physical Geography, Natural History, and Ethic Philosophy, especially on the Earth and its Strata, Water, and the Ocean, the Atmosphere, the Changes of the Globe, Organic Bodies, and the Human Species*, 4to, London, 1778. This highly interesting work was published by subscription; and a French translation of it was added as a fifth volume to that of Cook's Voyage, 4to, Paris, 1778. 22. *Description of the Yerbua Capensis, Swed. Trans.* 1778, p. 108. 23. *Translation of* Von Troil's *Letters on Iceland*, 8vo, London, 1780. 24. *On* Buffon's *Epochs of Nature, Göttingen Mag.* 1780, i. i. p. 140. 25. *On the Tiger-Cat of the Cape, Phil. Trans.* 1781, p. 1; the Felis Capensis, found from Congo to the Cape, and capable of being tamed like a cat. 26. *Historia Aptenodytæ, Commentat. Gott.* vol. iii. p. 121; the penguin, a genus peculiar to the southern hemisphere. 27. *Zoologia Indica Selecta*, Latin and German, fol. Halle, 1781, 4to, London, 1790; 2d edit. Halle, 1795. 28. *Account of a New Insect, Naturforscher*, vol. xvii. p. 206, Halle, 1782; a species of cancer. 29. *A Picture of England for* 1780, *continued to* 1783, 8vo, 1784; German, 8vo, Dessau, 1784; giving some amusing particulars of many of the principal public characters at the time of the American war, but frequently satirical, and sometimes unjust. 30. *Essays on Moral and Physical Geography*, 3 vols. 8vo, Leipsic, 1781, 1783; continued by his son-in-law Matthias Sprengel. 31. *A Collection of Memoirs relating to Domestic Economy and Technology*, 8vo, Halle, 1784. 32. *On the Albatross, Mém. Sav. Etr.* vol. x. p. 563; the Diomedea. 33. *History of Discoveries and Voyages in the North*, 8vo, Francfort on the Oder, 1784; English, London, 1786, Fr. Paris, 1788; containing a most extensive and elaborate collection of relations of all the attempts which had been made to explore the arctic regions. 34. *Project for abolishing Mendicity, especially at Halle*, 8vo, Halle, 1786. 35. *Enchiridion Historiæ Naturali inserviens*, 8vo, Halle, 1788; an extremely useful collection of definitions of the terms employed in the description of birds, fishes, insects, and plants, after the manner of the *Philosophia Botanica* of Linnæus; it is dedicated to his son George, by whose infantine curiosity he was first impelled to the study of natural history; and it was chiefly arranged during the leisure hours of his voyage round the world. 36. *A Memoir on the Badjar Cit. Mém. Acad. Berl.* 1788, 1789, p. 90; the Manis pentadactylus. 37. *Magazine of Modern Voyages and Travels, translated from various languages, with Remarks*, 16 vols. 8vo, Halle, 1790, 1798. 38. An edition of *Bergius über die Leckereyen*, a work on diet, with notes by Forster, Kurt, and Sprengel, 2 vols. 8vo, Halle, 1792. 39. *A Letter to Schreber on the Persea, Magazin für die Botanik*, vol. v. p. 234. 40. *Onomatologia nova systematis oryctognosiæ vocabulis Latinis expressa*, folio, Hal. 1795, 1 page. 41. *Observations and Truths united to Probabilities, or Materials for a new Essay on the Theory of the Earth*, 8vo, Leipzig, 1798; one of the last of our author's publications, which is considered as a good elementary work on geology.

(Sprengel's *Memoir;* Eyries in *Biographie Universelle*, vol. xv. 8vo, Paris, 1816; Aikin's *General Biography*, vol. iv. 4to, London, 1803; Chalmers's *Biographical Dictionary*, vol. xiii. 8vo, London, 1814.) (L. L.)

FORSTER, *John George Adam*, commonly called *George*, a distinguished naturalist and circumnavigator, the son of John Reinhold Forster, was born at Dantzick in 1754, and enjoyed, in his earliest youth, the advantage of his father's assiduous and affectionate instructions, by which he profited so rapidly, that he was capable, at the age of ten years, when he went with his father into Russia, of ascertaining the species of a plant by comparing it with the Linnæan description. He was for a short time at a school in Petersburg. Upon his arrival in London, he was at first placed in a merchant's counting-house, but soon found his health unequal to the employment, and followed his father to Warrington, where he continued his studies at the academy with so much application, that he became a perfect master of the English language, and otherwise distinguished himself by the strength of his memory and the vigour of his imagination, at the same time that he assisted his father in giving lessons in French, and in completing a variety of translations of voyages and travels. He also accompanied his father, together with Sparrman, in the arduous engagement of making all kinds of physical observations in the circumnavigation of the globe; and he was particularly employed in delineating the various objects of natural history which were discovered. After his return he was elected a fellow of the Royal Society; but he soon quitted England to settle at Paris. In 1779, however, he was appointed professor of natural history at Cassel; and, in 1784, he was nominated to a similar situation in the University of Wilna, where he took a degree of doctor of physic; but he found little satisfaction in residing amongst a people so imperfectly civilized. The empress of Russia had engaged him to take an important part in a new voyage of discovery which she meditated; but the design was abandoned upon the commencement of the war with the Turks. He was next invited by the elector of Mentz to accept the appointment of president of the university newly established in that city, and he was residing there at the time when the French army entered it. Being a declared republican in his political principles, he was dispatched as an envoy to Paris to solicit the incorporation of Mentz with the French republic; but during his absence the Prussian troops retook the city, and he lost the whole of his property, including his numerous manuscripts. He had married a Miss Theresa Hayne, and had one daughter as early as 1788; but, at a subsequent period, his wife's conduct gave him great reason for uneasiness; and though he affected to despise what he called the prejudices of social life, and to excuse her infidelity, and even attempted to facilitate her union with a more favoured admirer, still the affair in reality affected him deeply, and he resolved once more to leave Europe, as if in search of the waters of oblivion; and he was actually preparing for a voyage to Thibet, when his health was subdued by the ravages of a scorbutic disorder, and he died on the 13th February 1792. Besides the assistance which he rendered his father in many of his literary undertakings, he was also the author of a variety of separate publications under his own name.

1. *A Voyage Round the World in his Britannic Majesty's Ship Resolution, commanded by* Captain James Cook, *during the years* 1772, 1773, 1774, and 1775, 2 vols. 4to, London, 1777; in German, 2 vols. 4to, Berlin, 1779, 1780, and 3 vols. 8vo, 1784. The style of this work is rather more animated and poetical than that of the official account of the voyage; the second volume is considered as the best written, and the freest from affectation and false sentiment. 2. Mr Wales, the astronomer of the expedition, published some remarks on the work, which occasioned a *Reply to* Mr Wales's *Remarks*, 8vo, London, 1778, in which the author declares that his father had no concern whatever in the book, but he admits that he had committed some inaccuracies. 3. *A Letter to the* Earl of Sandwich, 4to, London, 1779. 4. His *Answer to the Authors of the Literary Journal of Göttingen* exhibits considerable warmth of language, but candidly admits some errors; it excited some further animadversions from Professor Meiners, who declared himself the author of the criticisms. 5. In 1787 he published at Berlin, in 4to, *A Translation of* Captain Cook's *Third Voyage, performed in* 1776–1780, with an introduction and other additions. 6. *A Description of the Gentiana saxosa, Swedish Trans.* 1777, p. 183. 7. *Life of* Dr Dodd, 8vo, Berlin, 1779. 8. *Preface to* Sparrman's *Travels,* 8vo, Berlin, 1784. 9. He undertook, together with Professor Lichtenberg, the publication of the *Göttingen Magazine,* which was continued from 1780 to 1785, and published in it, amongst other essays, *A Description of the Red Creeper, or Certhia coccinea of Owhyhee,* i. vi. p. 346. 10. *Experiments with Vital Air,* vol. iii. ii. p. 281; examining its effects on glow-worms. 11. *A Decad of New Plants,* N. Act. Upsal, vol. iii. 1780, p. 171. 12. *On Pygmies,* Hessiche Beyträge, vol. i. p. 1, 1785. 13. *History and Description of the Bread-Fruit Tree,* p. 208, 384; also separately, 4to, Cassel, 1784. 14. *Florulæ Insularum Australium Prodromus,* 8vo, Göttingen, 1786. 15. *Fasciculus Plantarum Magellanicarum,* Commentat. Soc. Gött. vol. ix. p. 13. 16. *Plantæ Atlanticæ,* p. 46. 17. *Miscellanies, or Essays on Moral and Physical Geography, Natural History, and Moral Philosophy,* 6 vols. 8vo, Leipsic and Berlin, 1789–1797; the last two volumes are posthumous, and chiefly of a political nature. 18. *Picture of the Lower Rhine, Brabant, Flanders, Holland, England, and France,* taken in the year 1790, 3 vols. 8vo, Berlin, 1791–1794; Dutch, Haarlem, 1792, 1793; French, called *Voyage Philosophique,* 2 vols. 8vo, Paris, 1795, 1796. This work contains many interesting remarks on manners and on the arts, showing that the author possessed very extensive information, as well as originality of talent; but there is too much affectation of sentiment, and an injudicious display of hostility to Great Britain. 19. *Historical Remembrances of the Year* 1790, 8vo, Berlin, 1793. There are also several political pamphlets of a temporary nature, which could add little or nothing to their author's fame; and a few scattered memoirs in different periodical publications. He was also concerned in the *Collection of Voyages* published by Professor Sprengel; and, together with Pallas and others, in an edition of Martini's *Dictionary of Natural History.* Indeed, his life, though short, was one continued scene of literary activity; but his application to the labour of compilation was too unremitting to allow him to concentrate the whole force of his mind on the performance of any one great original work of genius. The *Sketches of the Mythology and Customs of the Hindoos* were written by another author of the same name.

(*Life* by Pougens; J. R. Forster in *Jacobi's Annals,* and in the *Dedication of his Enchiridion;* Eyries in *Biographie Universelle,* vol. xv. 8vo, Paris, 1816; Aikin's *General Biography,* vol. iv. 4to, London, 1808; Chalmers's *Biographical Dictionary,* vol. xiii. 8vo, London, 1814.) (L. L.)

FORT, in the military art, a small fortified place, environed on all sides with a ditch, rampart, and parapet. Its use is to secure some high ground, or the passage of a river, to make good an advantageous post, to defend the lines and quarters of a siege, and the like. Forts are made of different figures and dimensions, according as the peculiar nature of the ground requires. Some are provided with bastions, others with demi-bastions; some are of a square form, others pentagonal, and others again are stellated, having five or seven angles. A fort differs from a citadel in this, that the latter is built to command some town.

Vitrified FORTS. This name has been given to certain remarkable ruins, situated for the most part on the tops of certain hills in the Highlands and northern parts of Scotland. They were first discovered about the year 1773, by Mr Williams, an intelligent mineral surveyor, who published an account of them some time afterwards. These singular structures derive their appellation of vitrified from the circumstance of the stones composing them presenting the appearance of having been melted or fused by means of fire, thus forming a solid mass of a glassy structure, somewhat resembling volcanic lava, or the refuse of a furnace. The single fact of their vitrification is the only characteristic applicable in a general sense to the whole of these forts. In form, size, and situation, they present every variety. Some of them are round or elliptical, whilst others are in the form of squares or parallelograms. In magnitude they vary from a few yards to some eighty or ninety in length, whilst their breadth differs in a proportional degree. The walls, likewise, as might have been expected, vary much in thickness. Some of them are only two or three, and others are about twenty feet in breadth. In height they also differ considerably, having apparently in some instances been twelve feet, and in others not a third of that height. In one or two instances there are a series of walls, two or three in number, enclosing the same area of ground, with a space between each of the works sufficiently large to admit of active defensive operations on the part of those who occupied the place. Their vitrification is very irregular. Occasionally it does not extend a few feet above the ground on which the fabric stands, nor penetrate beyond the surface, whilst in a few instances it rises to the height of ten or twelve feet, and passes inwards to a considerable extent on both sides. Sometimes only isolated parts of the walls show traces of vitrification, and that too but on one side; in other instances the process appears to have been completed with elaborate care, as the effects of the heat extend externally and internally over the greater part of their surfaces. They are for the most part placed, not upon the highest elevation of the country where they are situated, but generally in a commanding position; and they are found sometimes upon the sea-shore, and sometimes many miles inland. In general their structure displays nothing like regular masonry; that is, the stones have not been hewn into symmetrical shapes and cemented together, as is the case in the more modern structures of the same country. A few of them have regular causeways leading up to them, and many are furnished with wells, an indispensable requisite for a garrison. Such is a general description of these singular erections, which have for more than half a century excited so much curiosity and interest.

After the discovery of Mr Williams, the ingenuity of the learned was turned to their probable origin, and several theories and conjectures were hazarded by various individuals upon the subject. By one party they were declared to be of volcanic origin, whilst another contended that they were works of art. Of the latter opinion was Mr Williams himself, who not only declared them to be the result of human ingenuity, but speculated upon the manner in which they were constructed. But before adverting to any of the theories which have been advanced, we shall give a description of the most remarkable of these forts, and this, as far as possible, in the language of those individuals by whom they were examined.

Dun MacSniochain, which lies in Argyleshire, is very fully described by Dr Macculloch.[1] "It is situated on a small rocky hill, which forms a kind of island in the plain, of a narrow prolonged shape, and scarped all round, except at one extremity, which affords access to the summit and the fort. The height of this hill or rock above the plain seems to be about forty or fifty feet; and it is, even in the modern military sense, a strong position. It is important to remark, that the rock consists of limestone and slate intermixed, the plain itself being chiefly alluvial, and the nearest hill and rocks being of trap, and of that puddingstone so well known to all travellers, which also abounds in the vicinity of Oban. That stone is itself formed of fragments of various trap rocks, and is remarkable for its ready fusibility, while the rock on which the fort stands is of an infusible nature. The fort itself is so contrived as to occupy nearly the whole summit, which is about 250 yards long, and consists of three distinct parallelogramic enclosures. The dimensions of these are as follows, as nearly as could be measured by pacing. The outer is about thirty yards long and about twenty-four broad; the next is about thirty-seven, with a similar breadth; and that at the farther extremity is about fifty-six yards in length, but being imperfect, it may formerly have been longer. Besides this, between the first and second works there is a transverse wall which reaches from the one precipitous face to the other, so as, when entire, to have cut off the communication from without to the two inner works. The circumferences of the two inner enclosures make collectively a line of about 260 yards, which, according to the modern military computation for a redoubt, would contain more than 500 men. The external work would dispose of about a hundred more. Hence it is plain that this must have been a military work of some consequence, as capable of holding a large garrison." The doctor goes on to show the eligibility of this place as one of military defence; and observes, that the walls were probably twelve feet thick. He continues, "when it is said that the walls here or elsewhere are vitrified, it must not be supposed that they form a solid mass of glass or slag. That condition is very various in different specimens throughout Scotland, and if it is here more perfect than in many, it is less so than in some others. To speak more accurately, many of the stones which form the walls are more or less perfectly slagged or scorified; so that while some have been thus changed throughout, the surfaces only of others are affected, while others again, consisting of less fusible materials, are only burnt. A certain proportion has escaped the fire altogether, or has never been exposed to it; and if we may judge from the ruins, this has taken place chiefly towards the upper part of the wall. The general result, however, is, that in some parts the wall forms a solid mass, but of an irregular composition, consisting of scoria, slag, burnt stones, and stones scarcely altered, united together, but with vacant intervals; while in other places it is separable into lumps of various sizes, and into single stones."

The next vitrified fort described by Dr Macculloch is that of Dunadeer.

"The hill of Dunadeer, having an elevation of about 600 feet[2] from the irregular plain on which it stands, with a steep acclivity all round, has a flat oval summit, which is entirely occupied by the enclosure, so as to form a strong military position. Though much ruined, and consequently obscured, having apparently been used as a quarry for building a more modern castle in the same spot, it is not difficult to trace either the dimensions or the disposition of the original work. The form is a parallelogram, of which one extremity is curved, so as to be nearly semicircular, and its longest side is about fifty-eight yards, the shortest being about twenty-four. The thickness of the wall seems originally to have been eighteen or twenty feet; although, from the state and nature of the ruin, it is impossible to be very accurate in this particular. The highest remaining portion is about six feet above the present surface; and if one foot be added for the increase of soil, and two for the loss which it has sustained at the summit, to be computed from the ruined part at its foot on each side, we shall have eight feet as the probable original altitude.

"The materials of the hill are chiefly grey granite, an infusible rock; but there are scattered in the surrounding plain blocks of a black variety, which, from containing hornblende, is very fusible. To pass over the obviously more modern ruins at this place,[3] as not concerning the present question, there are at a certain stage down the hill the well-marked traces of a work which once seems to have encircled the whole. It is a kind of fortification well known to antiquaries as occurring frequently in the ancient British hill forts; and it resembles a modern military field work, as it consists of a single ditch and wall, the latter being formed of loose stones not vitrified. I consider this as part of the original defences, because a similar one is found on Noath.

"The materials in the vitrified wall are, as at Dun MacSniochain, partly roasted without adhesion, and partly vitrified, or glazed or scorified, in a similar manner. It is easy to see that the dark granite forms the vitrified and scorified substances; but, not to enter on the more minute details, which rather concern the chemist and mineralogist than the antiquary, but which are very interesting to them, I shall only further remark, that wherever stones not capable of vitrification themselves have undergone this change, it has been produced by the alkali of the wood used in the process; whence the glazed surfaces of many unvitrifiable substances.

"Now I remarked that at Dun MacSniochain the materials of the hill itself were not vitrifiable, but that a very fusible rock was present at a short distance, or scattered in fragments about the plain. The same is true here; and in both cases the forts are not erected out of the materials nearest at hand, which are infusible, but collected with considerable labour from a distance. It is hence evident that the builders of those works were aware of the qualities of these various rocks, and it is equally evident that they chose the fusible in preference to the infusible, although with a considerable increase of labour."

---

[1] Macculloch's *Highlands and Western Isles*, vol. i. p. 283.

[2] This is an exaggeration. It is only about 400 feet high at the moat.

[3] This, we presume, refers to the remains of an oblong tower constructed of lime, mortar, stone, and fragments of the earlier vitrified fort, to which the opponents of Dr Macculloch ascribe a more modern date than belongs to the rest of the structure.

The next vitrified fort of consequence is that upon the hill called Noath, or Top of Noth, in Aberdeenshire. It is thus described by the same author:

"This mountain is the highest point of its own ridge, rising to the height of about 1800 feet above the level of the sea, and of 300 above any part of the surrounding ground, with a steep acclivity. The summit is a plain; and, as at Dunadeer, that plain seems to have regulated the size of the fort, as it occupies the whole space; an arrangement which is equally found at Dun MacSniochain. Nothing can more clearly prove the military and common design of all these works, since they vary in form and size according to the ground they stand on, and are so contrived, just as a military work would be in the hands of a modern engineer, that they may command all the points of access, and prevent the enemy from advancing any where under cover. . . . The area on Noath is nearly twice as large as that on Dunadeer, yet the same system is followed; and in Dun MacSniochain, as I already showed, though the mode of occupying the ground is different, the principle of a complete command is equally kept in view; while other variations are made for the purpose of conforming to the peculiar shape of the hill."

"The enclosure on Noath is a long parallelogram of about ninety by thirty-two yards, slightly rounded at the angles; and it contains a well. Hence also we may conclude that this was a station and a garrison. An entire deficiency of the wall at the eastern side seems to indicate the entrance or gateway; a notion confirmed by its being continuous with a spacious causeway that extends a considerable way down the hill. That connexion also leads us to conclude that this causeway was not a posterior work, but that it originally belonged to the fort. It is made of laid stones, of considerable bulk, with great care and strength, resembling a Roman road; and it is remarkable that a similar causeway leads to the fort of loose stones on the top of Ben-na-chie.

"At Noath, too, as at Dunadeer, there is a similar field-trench and wall, or outwork, on the declivity of the hill; and, though much obscured, it seems also to have formerly surrounded the whole. In both cases it seems to have been intended as a covered-way, to retard the attack on the body of the place. The vitrified enclosure is far more perfect here than in any of these works in Scotland; and it is infinitely more remarkable, since, being unencumbered with soil and vegetation, scarcely even bearing a lichen, we see at a glance the whole effect of its blackness, its bulk, its regularity, and its extent. We may indeed wonder how any one could have imagined such a work the produce of a volcano, and not less how any one capable in the least degree of observation or reasoning could have conceived it the effect of beacon-fires.

"The parts of the wall which have been most perfectly vitrified are, as might have been expected, the most entire: where highest, they measure eight feet from the ground, and the accumulation of soil at the base would justify the addition of two or perhaps three feet more in some places. That rubbish prevents the breadth from being correctly estimated, but this seems, as at Dunadeer, to have been eighteen or twenty feet. And if from that rubbish we may form an estimate of the total height of the wall before dilapidation, and before the growth of soil below, it may probably be taken at twelve feet. I must also remark, that the fallen rubbish, where the standing and vitrified part is eight feet high, consists of unvitrified stones; so that here, as at Dun MacSniochain, and in other examples, the wall, after having been vitrified to a certain height, seems to have been raised by some courses of dry masonry to its total altitude." The state of the various materials which have been here exposed to the fire is so similar to that of those belonging to Dun MacSniochain and Dunadeer, that it is unnecessary to repeat the description.

On the hill of Knockfarril, which lies to the south of the valley of Strathpeffer, two miles west from Dingwall in Ross-shire, there is a vitrified fort. It is a remarkable one, both on account of its size, and because it was one of those which arrested the attention of Mr Williams, the discoverer of these structures. The hill of Knockfarril forms part of a double ridge which bounds the valley of Strathpeffer on the south, and separates it from the valley of the river Conan. The sides of the hill are steep, but at the eastern and western extremities the ascent is comparatively easy. The area upon the top is about a hundred and thirty-five yards in length by about forty-five yards in medium breadth, and is a good deal inclined towards the west. Round the area, and close to the edge of the hill, are found masses of stones cemented together by melted matter, and irregular both in position and in size. The vitrification is superficial, extending only a short way amongst the stones. According to Mr Cardonnel, one of the earliest inspectors of this place, "the enclosure is a hundred and twenty feet long and forty broad within the walls, strengthened on the outside with works at each end. A range of habitations seems to have been erected against, or under the shade of, the outward wall, of which those on the south side seem to have been higher and larger than those on the north. There are two wells in the middle, which, on being cleared out, filled with water. On the skirts of the hill to the south are many detached buildings, which, from the stratum of dung found on removing the ruins, appear plainly to have been used for securing the cattle. This place seems to have been anciently of consequence, and the residence of some powerful chief, from a road which leads through the hills to the north-west sea. To the east of the works are a number of vitrified ruins, extending for a considerable way along the ridge of the hill. The end next the fort seems to have joined the outer wall, and consisted either of two parallel walls, closed above, with a passage between them under cover, or a high wall broad enough to walk on. In this wall there is the vestige of a break about the middle, over which a bridge has been laid, to be drawn up or removed as occasion might require."

Mr Williams caused several cuts to be made across the area in different places, in which, Sir George Mackenzie[1] observes, a considerable quantity of rubbish is to be seen. "This rubbish," says he, "appears to have been collected for the purpose of extending or forming the area on the top; and it would seem that much labour had been bestowed in accomplishing in this manner what might apparently have been effected more easily by cutting down part of the summit." The vitrified masses appear in many instances to have been displaced; and it seems pretty evident that the rampart was originally constructed with as much regularity as the nature of the materials would admit, both in order to render it more durable, and also to make it serve the purposes of defence.

---

[1] Article Forts, Vitrified, in Edinburgh Encyclopædia.

The fort next in importance to that of Knockfarril is situated upon the hill of Craig-Phaidrick, near Inverness, "which," according to Cardonnel, "has this peculiar circumstance, that there appears to have been two vitrified walls quite round the area. The inner one seems to have been very high and strong, the outer wall but low; probably the space between was intended for securing their cattle, as there are no remains of dry-stone buildings, such as are found near the rest. Several parts of this outer wall appear quite entire, sticking to the firm bare rock, where it was first run. The area within the inner wall is near eighty paces long and twenty-seven broad." Of this fort we have an account by Mr Tytler, afterwards Lord Woodhouselee. The hill itself is a small conical eminence, forming the eastern extremity of that ridge of mountains which bounds Loch Ness on the north-west side. It is situated about a mile to the north of Inverness, and is accessible on two different quarters, namely, the west and south-east; the former affording entrance by a narrow level ridge joining the hills on Loch Ness, and the latter by an easy ascent from the high ground above Inverness. On approaching the hill from the west, the traveller first meets with a road cut through the rock from the bottom to the top, in most places ten feet broad and nearly as many deep, winding, for about seventy feet, in an easy serpentine direction, by which he gains an ascent over a steep rock otherwise quite inaccessible from that quarter. In ascending by this road there appears, towards the middle, on the right hand, a small platform overhanging the passage, and inclining by a very gentle declivity to the very edge of the rock. Four enormous stones, which are placed upon the platform, and on the edge and extremity of it, have evidently been guided by art into that position, it being impossible that they could have rested there had they been rolled down from the higher parts. The obvious reason for placing them in such a position has been, that on an alarm of danger they might be projected into the path below, which could be effected by the efforts of a very few men; and when done, the passage would be entirely obstructed, or at least rendered so difficult that it could be defended by a few men against any number of assailants. Some other large stones are placed on an eminence to the left, probably with a view to block up a hollow channel, by which an enemy might have attempted to ascend. When the traveller reaches the top of the hill, a few feet below the rampart which crowns the whole, there appears an outward wall, approaching on the sides of the hill so near the upper rampart as to have only a trench of ten or twelve feet wide between them. This outward wall is in some places so low as to be almost level with the rock, though in other places it rises to the height of two or three feet; but even where lowest, it may be traced by a line of vitrified matter sticking fast to the rock all along, and nearly of the same breadth, which is about nine feet. The remains of this wall are strongly vitrified, excepting in one place on the north side, where, for about seventy yards, the rampart is formed only of dry stones and earth. At the east side, where the hill is more accessible, there is a prodigious mound of vitrified matter above forty feet in thickness. At the south-east corner, and adjoining to this immense mound, is an outwork, consisting of two semicircular vitrified walls, with a narrow pass, which appears to have been the principal entry to the fort, cut through in the middle.

The inner wall, surrounding the summit of the hill, encloses an oblong level area of about seventy-five yards long and thirty broad, rounded at each of the ends like the outward wall. It is of considerable height, and nearly of the same thickness with the outward one. It has some appearance of having been defended with four turrets or bastions; but the traces are so imperfect that Mr Tytler does not lay much stress on his observations in this respect; a number of small tumuli of earth, with a stone in the centre, were more discernible. On the east side a portion of the internal space appears separated from the rest by two ranges of stones fixed strongly in the earth, and forming a rectangular parallelogram. "This separation," says our author, "is immediately discernible by the eye, from this circumstance, that the whole of the enclosed summit has been most carefully cleared from stones, of which there is not one to be seen, unless those that form this division, and the single one in the middle of the circle of tumuli above mentioned. What has been the design of this separated space it is difficult to conjecture. It might perhaps have marked the residence of those of a higher rank, or served as a temple for the purposes of devotion." At the east end of the large area on the summit is a well of about six feet in diameter, which has probably been sunk very deep in the rock, though now it is filled up with rubbish to within a yard of the top.

In the parish of Meigle, in the county of Perth, there is a hill called Barryhill, which seems to have been fortified with particular care. "Its summit," says Dr Playfair, by whom it has been described, "was levelled into an area a hundred and eighty feet long and seventy-two broad. Around the area a mound of earth was raised from six to eight feet high and ten to twelve broad at top. On this mound a wall of freestone was built, without any cement whatever. The foundation of the wall was composed of rough granite, and still remains. It is of the same breadth with the summit of the mound, but the height of the wall cannot be known. Gordon's estimate of it is very erroneous. Among the ruins there are several pieces of vitrified stone, but these vitrifications must have been accidental, as they are few and inconsiderable. Along the west and north borders of the area are barracks, or huts of dry stone, and sufficiently sheltered by the mound and wall; but no structures of this sort can be traced in the south part of the area. As the north and west sides of the hill are steep, and of difficult access, there was no need of an outer ditch in these quarters; but towards the south and east, where the hill gently slopes, there is a ditch ten feet broad and twelve to sixteen feet below the foundation of the wall. At the south-east extremity of the fort a narrow bridge was raised over the ditch, eighteen feet long and two broad, except towards each end, where the breadth was increased. It was composed of stones, laid together without much art, and vitrified above, below, and on both sides, so that the whole mass was firmly cemented. That an opening was left below, after the process was finished, is doubtful. On the upper part of the bridge a stratum of gravel was laid, to render the passage smooth and easy. This is the only part of the fort intentionally vitrified. A few yards distant from the ditch there is an outer wall, the foundation of which is about eight feet lower than the summit of the mound. The approach to the fort is from the north-east, along the verge of a precipice; and the entrance was secured by a bulwark of stone, the ruins of which are extant. There is no vestige of a well within the fort; but westward, between the basis of the mound and the precipice, there was a deep pond or lake, recently filled up by the tenants in that neighbourhood. About a quarter of a mile eastward, on the declivity of the hill, there are some remains of another oval fort, of less extent than the preceding, consisting of a strong wall and ditch. Tradition says that there was a subterraneous communication between these forts, which is not improbable."

In reference to this description of Dr Playfair, Sir George Mackenzie observes,[1] "On going to examine what Dr Playfair has called a bridge, I found that this considerable mass consisted of primitive rock stones vitrified. It had not the slightest resemblance to a bridge, either in its form or apparent use." He goes on to state that its position is in the bottom of the trench, between the summit and the outer rampart; and then observes,[2] "The singularity of Barry Hill is in the vitrified matter being in the trench. If it shall afterwards be found that the whole extent is composed of melted stones, this circumstance also will be remarkable, as it will indicate an intended collection of vitrifiable stones. But if detached vitrified masses only shall be found, then their presence may be presumed to have been accidental."

Near Creich, in the county of Sutherland, a ridge projects into the Frith of Dornoch, terminating in an abrupt precipitous hill. The ridge runs nearly east and west, and the top is of difficult access; whilst the summit, the outline of which is very irregular, is encircled by a rampart of loose stones. Within this there is another rampart of the same kind, which encloses the remains of a building constructed of stone and mortar. It is about thirty feet square, the walls being three feet thick, but not now more than four feet in height. There is a spring of water on the outside of the rampart, and at a short distance within it there is a well, which has been filled up. What renders this ruin remarkable is, that within the enclosure of the rampart, and at one end of it, there runs across the whole summit a mass of stones displaying abundantly the marks of fire; and the vitrification, according to Sir G. Mackenzie, is entirely confined to this part of the hill. The surface of the hill within this rampart is uneven and rocky; and that part of it which is crossed by the vitrified mass is rather lower than the eastern portion.

Near the church of Amwoth, in the county of Kirkcudbright, there is a steep rocky hill about three hundred feet high, the summit of which has been fortified. "The top, which forms a level area thirty paces long and twenty broad," says the Rev. Mr Gordon, by whom it has been described, "is nearly surrounded with an irregular ridge of loose stones, intermixed with vast quantities of vitrified matter. The stones, consisting of the common blue schistus of the country, have been softened, twisted, and partly fused by the fire. These heaps of loose stones and vitrified matter are scattered irregularly over the top of the fort, and exhibit no appearance of having ever formed a continued wall. The vitrification is only partial and superficial, and seems to have been the accidental effect of large fires kindled on these high rocks, either for some domestic purpose, or for signals to alarm the country on the approach of an enemy. It was formerly believed that these vitrified forts were peculiar to that part of the island which is north of the Forth. But besides the one described above, there are two others in the country, and they all command a very extensive prospect of the sea."

In the island of Bute, in the parish of Kingarth, there is a vitrified fort; and in Cantyre, at the entrance of the bay of Carradale, on a small island, about a rood of ground is enclosed by vitrified masses. Others have been observed in Argyleshire, particularly one on the hill of Dunskeig, which commands the entrance of Loch Tarbert. On the same hill, ramparts have been constructed with dry stones, without any vitrification.

On the hill of Laws, which is situated near the village of Sturdymuir, a few miles north-east from Dundee, there is a vitrified fort. The area on the summit is 133 yards in length and 66 in breadth, and all round it are to be seen the vestiges of a broad rampart, and large masses of vitrified stones. About four miles east from Forfar is the castle-hill of Finhaven, the vitrifications on which have been compared by Dr Anderson to the effects of fire in a lime-kiln. The enclosed area is about 140 yards long and upwards of forty broad, and the walls in some parts of this fort have been laid bare, so as to appear at least ten feet high. There is no perfect description of the extent of the vitrification, but Mr Tytler says that marks of it are visible all round the summit. Dr Anderson describes it as appearing here and there in horizontal or nearly horizontal streaks. Dr Jamieson informs us that the stones are in courses, and banded together, and that they have been very unequally and irregularly affected by the fire, and many of them not at all. Seven or eight varieties of stone appear to have been employed. On this hill there are several cross walls, and the vestiges of outworks, which altogether present much that is interesting to the curious in such subjects.

It is impossible in this place to describe all the vitrified ruins, amounting to about fifty, and extending over Perthshire, Forfarshire, Kincardineshire, Aberdeenshire, Banffshire, Morayshire, Inverness-shire, which contains an immense number, Ross-shire, Cromartyshire, Argyleshire, Buteshire, Berwickshire, and Galloway. Dr Hibbert, who has laboured with great industry in attempting to solve the problem of their probable origin, in a paper which was read to the Society of Antiquaries of Scotland in 1831, informs us that he had discovered masses of vitrified matter at Elsness, in the island of Sanday, one of the Orkneys. Of these curious remains, which he calls vitrified cairns, or beacon cairns, he counted more than twenty. They are of a round shape, from three to five yards in diameter, and elevated from two to three feet above the surface of the ground. The stony fragments of which they are composed appear to have been collected from the beach, and consist of what geologists call an argillaceous schist. Their fusibility they derive chiefly from the feldspar, or rather the alkali, which they contain.

At Jedburgh, and we believe in other parts of Scotland besides those above mentioned, vitrified matter has been found, but only in small quantity, and not presenting any appearance of having formed part of a building.

Not long after these structures were discovered by Mr Williams, the notion that their vitrification was of volcanic origin was started, and soon became very prevalent. It was embraced by Mr Pennant, the eminent naturalist, who came to this conclusion after an examination of Craig-Phaidrick. A similar view was adopted by other individuals; and the appearance of the hill in question, as well as that of some others of these forts, is not ill calculated to favour this opinion. But as other ruins of the same kind came to be discovered, and an appearance of regular construction began to develop itself, another and a more rational hypothesis was advanced. In the year 1777, Mr Williams published a pamphlet, in which the validity of the volcanic theory was opposed. This author first assured himself, on the authority of Dr Black, the celebrated chemist, that many varieties of the rocks of Scotland were fusible by artificial means, and then advanced the theory that vitrification was artificially induced, as a cement for the consolidation of ramparts of loose stones. He supposed that they were constructed in the following manner: Two parallel dikes of earth or sod being raised in the direction of the intended wall, with a space between them sufficient for its thickness, the fuel was put in and set on fire. The stone best adapted for this purpose, called the *plum-pudding stone*, is everywhere to be found in the neighbourhood. Stones of this description were laid on the fuel, and, when melted, were kept by the frame of earth from running off; and by repeating the operation, the wall was raised to a sufficient height. Amongst others who adopted the theory of Mr Williams, was Dr Anderson, who improved upon it by suggesting that a peculiar kind of vitrifiable ore was employed to promote the vitrification.

---

[1] *Archæologia Scotica*, vol. iv. p. 184.

[2] *Archæologia Scotica*, ibid.

In a paper published in the year 1827, in the Transactions of the Royal Society of Edinburgh, another hypothesis was advanced by Lord Woodhouselee, who had some time before made an extensive survey of the vitrified forts. Mr Williams, probably from too partial an examination, had erroneously asserted that every stone composing a vitrified fort had been acted upon by the fire; but Lord Woodhouselee finding that the fact was not so, and that many parts of the walls showed no marks of vitrification, began to doubt the theory of Mr Williams. Whilst he agreed with him in thinking these structures artificial works, he differed from him in supposing that their vitrification was accidental. It was not, he said, in their construction, but in their demolition, that they were vitrified; and this may be supposed to have occurred from many circumstances. In the rude state in which Scotland existed at the early period to which the erection of these forts must be attributed, it is probable that their buildings, both for habitation and defence, would be frequently constructed of loose stones of an irregular shape, which, of themselves, could scarcely form a wall of any tolerable strength. Hence it became necessary to employ wood as well as stone in their construction. This kind of building, then, in our author's opinion, was begun by raising a double row of palisades or strong stakes in the form of the intended structure, in the same way as in that ancient mode of building described by Palladio under the name of *riempiuta a caffa*, or coffer-work. These stakes were probably warped across by boughs of trees laid very closely together, so as to form two fences running parallel to each other at the distance of some feet, and so close as to confine all the materials, of whatever size, that were thrown in between them. Into this intermediate space, his lordship supposes, were thrown boughs of trees, earth and stones of all sizes, large or small as they could quarry or collect them. Very little care would be necessary in the disposition of these materials, as the outward fence would keep the mound in form. In this way it is easy to conceive that a very strong bulwark might be reared with great dispatch; which, joined to the natural advantage of a very inaccessible situation, and that improved by artful contrivances for increasing the difficulty of access, would form a structure capable of answering every purpose of security or defence. The most formidable attack against such a building would be fire, which would no doubt be always attempted, and often with success, by an enemy who undertook the siege. If the besiegers prevailed in gaining an approach to the ramparts, and, surrounding the external wall, set fire to it in several places, the conflagration must speedily have become universal, and the effect may be easily imagined. If there happened to be any wind at the time to increase the heat, the stony parts could not fail to come into fusion; and as the wood burnt away, sinking by their own weight into a solid mass, there would remain a wreck of vitrified matter tracking the spot where the ancient rampart had stood; irregular, and of unequal height, from the fortuitous and unequal distribution of the stony materials of which it had been composed.

The fifth and last theory is, that the vitrification of these forts was the result of beacon-fires. This opinion first obtained supporters amongst the contributors to Sir John Sinclair's *Statistical Account of Scotland.* It was afterwards advocated by Sir George Mackenzie in the article previously referred to; and latterly by Dr Hibbert, who has published several ingenious papers on the subject in the *Archæologia Scotica.* Such are the various hypotheses which have been advanced explanatory of the singular phenomena of vitrified forts. To present any thing like a complete view of the arguments which have been produced in support of each, would occupy more space than can here be allotted to the subject; an abstract, therefore, of those which are most striking can only be given. In general those who have considered the subject at all are divided into two classes; namely, those who support the theory of Mr Williams, and those who advocate the beacon-fire theory. Amongst the most eminent of the former class is Dr Macculloch, who published a memoir upon the subject in the Transactions of the Geological Society of London, and also treated of it in his work on the Highlands and Western Isles of Scotland.

But, first, with respect to the beacon theory. That at a very early period of Scottish history mountain fires were lighted for the purpose of alarming the country when an enemy appeared upon the coast, is an undoubted historical fact. The primary assumption is therefore undeniable. With respect to their origin, many of those who support the hypothesis that the vitrification of these forts is the result of beacon-fires, have offered conjectures as to the date of their erection. Upon this subject Dr Hibbert observes,[1] "The coasts of Scotland began to be annoyed by the predatory visits of the Vikingr (Sea-kings) about the end of the eighth century; but it was not probably until the Scots had obtained a complete ascendancy over the Picts, by which both were united under one government, that systems of beacons were formed to provide against the sudden descent of the Scandinavians, who invaded them from the Danish or Norwegian shores, or from countries which they subsequently colonized, namely, from Shetland, Orkney, Caithness, Sutherland, the Hebrides, Ireland, or the Isle of Man. The Murray Frith, as we learn from ancient Sagas, was one of the most convenient landing places for the Northmen; and hence we must look to this locality for the greatest proportion of vitrified sites. The number of such as have been traced within sight of each other, in a direction east to west from Banff to Dingwall, and in a direction north to south from Cromarty to Fort Augustus, may be estimated at twenty; but it is probable that their actual amount will be eventually found to be much more. Two vitrified eminences appear near Huntly, connected apparently with the line of coast extending from Kinnaird's Head to the mouth of the Dee. More south, a chain of vitrified sites, nine or ten in number, appears to have conveyed signals from the line of coast which stretches from Kincardine to the Tay, being prolonged from Stonehaven or Dundee to the neighbourhood of Dunkeld or Crieff. On the west coast, again, we find similar vitrified sites at Bute, Cantire, Isla, Loch Etive, Loch Sunart, Fort William, or at Arisaig. The number which subsists on the west yet remains to be ascertained; about twelve have been enumerated. Lastly, at Galloway, three occur, apparently as signals against the marauding colonists of Ireland.

---

[1] *Archæologia Scotica*, vol. iv. p. 170.

"But it must be kept in view, that it is highly improbable that the original intent of the whole of these vitrified sites was that of affording convenient localities for beacon-fires. There is no necessity whatever, *cœteris paribus*, that signal lights, merely giving notice of the approach of an enemy from the sea, should be situated on fortified stations. It is not improbable, therefore, that the rude ramparts themselves might, at a still more remote period, have been erected by the oldest inhabitants of Albyn, namely, by the Caledonians and Picts; and hence their occasional or very partial vitrification would merely indicate the later use to which the eminences upon which they were situated had been applied, when the Scots, who succeeded to far earlier inhabitants, were called upon to repel new invaders from the sea."

Dr Hibbert goes on to remark, that after the Norsemen had acquired a permanent settlement in Scotland, and also in other places, they themselves became liable to sudden piratical descents from their own countrymen; to guard against which they instituted, in every country where their arms prevailed, still more perfect systems of beacon-fires, the wardenship of which was enforced by the most rigorous laws. This we are informed of by ancient Sagas, and edicts on the subject are found in many early codes of the north of Europe. From two ancient writers, Olaus Magnus and Snorro, passages are quoted, which go to prove that large trees were felled, formed into piles upon mountain tops, and then set fire to, for the purpose of giving intelligence to the country of a hostile invasion. These, however, obviously apply to countries upon the Norwegian coast in particular; but they may be extended to those portions of Scotland which were under the domination of the Norsemen.

The same writer further observes, that vitrification may in some cases have resulted from fires having been lighted in these forts during the observance of religious and other festivals. The custom of kindling immense fires on occasions of feasting was certainly common in ancient times; indeed, the custom of the Baaltein, or festival in honour of Baal, is observed in some districts even at the present time. He also supposes that many of the sites where vitrified remains occur were places of rendezvous for tribes or clans, upon public occasions of peace or warfare; and also that the ramparts afforded a shelter for cattle as well as for human inhabitants. Dr Hibbert sums up his evidence in support of the beacon theory by giving a list of the ancient forests of Scotland, from which it appears that the country was formerly in a densely wooded state, and hence afforded ample materials for kindling beacon-fires upon the grandest scale, and celebrating the rites of Baal, or any other object of worship, in a manner sufficiently flagrant to propitiate the favour of the most exorbitant fire-loving god of antiquity.

In the Transactions of the Society of Antiquaries of Scotland, vol. iv. are various papers relative to vitrified sites, which were read to the society by Dr Hibbert in the year 1831. These contain several communications from Sir George Mackenzie, Mr George Anderson, and others, in which the main principle, that these forts were beacon stations, is supported by an attempt to establish the fact that the hills on which they are found form a regular chain of signal stations which command each other. By this arrangement a fire kindled on one of them could be seen by those contiguous, and thus intelligence communicated throughout the whole line, on whatever part of the coast the enemy might make their appearance. This hypothesis was advanced by Sir George Mackenzie, in his article on vitrified forts in the Edinburgh Encyclopædia, where he also lays much stress upon the appearances exhibited by the hill of Dun Creich, in which, as formerly mentioned, only the singular wall which runs from one side to the other of the rampart shows marks of vitrification. The reason assigned for traces of fire being only partially visible in this and in all the other forts is, that the combustible matter was always placed so as to be sheltered from the wind. "To be satisfied," he observes, "whether the signal-fires should be kindled on or beside a heap of stones, we have only to imagine a gale of wind to have arisen when a fire was kindled on the bare ground. The fuel would be blown about and dispersed, to the great annoyance of those who attended. The plan for obviating the inconvenience thus occasioned, which would occur most naturally and readily, would be to raise a heap of stones on either side, of which the fuel might be placed to windward."

Such are the leading arguments produced in support of their doctrine by the advocates of the beacon theory. The most distinguished advocate of Mr Williams' views is Dr Macculloch, to whose works on the Highlands and Western Isles we have already referred. The doctor observes, with reference to the partial vitrification of the walls, that had the walls been the enclosures of beacon-fires, every stone from the summit to the base must have felt their effects alike. But the great variety found in the forms and sizes of these works, their obviously military and defensible character, and the enormous size of some of them, as for instance that at Noath, seems, in his opinion, to render the notion of their having been signal-stations scarcely worth refuting. "At Amwoth, in Galloway," he says, "the hill has been scarped by art, so as to form a deep ditch close to the foot of the wall. Nothing of this kind could have been required for a beacon; and it is further remarkable, that the transverse wall at Dun MacSniochain is a common expedient for defence in the ancient British works that occupy peninsulas or promontories; as at Castle Trereen, Zenor, and Tintagel, in Cornwall. The advanced covered-ways of Noath and Dunadeer, and the causeway of the former, would be equally unnecessary on such a supposition; nor, at Noath, could any possible purpose of a beacon have demanded or justified such an enormous work, whether we consider the area enclosed, or the height and thickness of the walls.

"To imagine an area of 2700 square yards covered with burning wood, and to conceive a wall that would have required the labour of many hundred men for weeks, built for no other purpose than to enclose what did not want enclosing, are dreams not deserving a serious examination. If a chemical argument were wanted in addition to these, it would be found in the fact, that though all this wood, a forest in itself, were collected and lighted, when a square yard would have served the purpose as well as two or three thousand, it would not vitrify its enclosure in the manner in which these walls are vitrified; as the current of air from without would, by cooling the external part, impede its action on the outside, where the fusion is as complete as within. It has been asserted that these vitrified forts actually did communicate in chains, or in connection, throughout the country. Nothing but a similar ignorance respecting these works and their places could have led to such an assertion; it is not the fact; in many instances it is physically, geographically, and optically impossible; and the mere supposition involves equal ignorance of the political state of Scotland in ancient times, or else hypothesis respecting its union under one organized government, which is purely gratuitous. Many of them indeed are placed in situations so low, or so entangled among hills, as to preclude all communication of this nature; as is the case in Isla, in Morven, in Ardnamurchan, in Galloway, and apparently along the course of the Bogie in Aberdeenshire."

Dr Macculloch goes on to observe, that the appearances of the burned and vitrified substances appeared to him to prove that a long-continued and intense heat had been applied, neither of which effects could have resulted from the burning down of a wall formed of stone and wood, as Lord Woodhouselee supposed was the case. The plan of constructing a species of furnace by means of earthen mounds, into which stones and fire were introduced till the structure was finished, not only, according to our author, answers all the conditions, and, among the rest, that of vitrifying the materials below more perfectly than the upper ones, but is confirmed as to its probability and efficacy by a practice in use in some parts of India. We are informed by a French engineer, that in that part of Asia houses of clay are burned into a solid brick, in this very manner and at this day, in order to prevent the effects of inundations. Dr Macculloch further observes, that the art seems to have been practised in England, though with a different end in view. Some years ago a house was demolished in Shropshire, part of which, of unknown antiquity, was covered with an entire crust of glass, apparently for the purpose of protecting it from the effects of the weather.

With respect to the antiquity of these forts, little can be advanced that is satisfactory. Our author offers a speculation, that if they were built by one people, in the widely-separated districts where they are found, they ought to belong to a time prior to the division of Scotland into a Pictish or Caledonian, and a Scottish or a Celtic and Norwegian dominion. Thus they should be referred to the aboriginal Celts, or first settlers of Scotland; that people whom the Pictish invaders found, and on whose defeat they settled themselves in the conquered country. The same writer concludes his observations by expressing a hope "that some future traveller in the East will find further reasons to prove that they are among the earliest military works of our oriental Celtic ancestors."

Such are the arguments brought forward by each of the parties in support of their theories as to the origin and design of vitrified forts. It must be confessed that a case perfectly satisfactory and free from doubt is made out by neither of them, although the balance of probability seems in favour of the opinion that they were regular military works, vitrified on purpose, for the sake of strengthening the walls at the time when cement was unknown. In support of this view of the case, we shall offer a few remarks.

The main question is, were these forts intentionally vitrified, for the purpose of cementing the walls together? or was the vitrification an accidental result of beacon-fires being lighted up within their enclosures? It would certainly be injudicious to advocate either theory exclusively. For if, on the one hand, we maintain that they were intended for places of strength, some of them are evidently too small, and would have been utterly useless for that purpose; and if, on the other hand, it be asserted that they were signal-stations accidentally vitrified by signal-fires being lighted there, then the size and elaborate construction of some of them indicate their adaptation to something of far more importance. Sir George Mackenzie observes: "We allow, that while these hills were chosen for signal-stations, they were also used as places of defence. And indeed it would have been strange if posts of so much importance had been left without the means of resistance. All have agreed that they were places of more or less strength, though perhaps such lofty and exposed situations were not well chosen for protracted warfare. Had they been merely places of retreat, an invading enemy would certainly overlook them, as he could overrun and pillage the country without the possibility of his being annoyed from them; or if there was any risk of his progress being interrupted, the situation of the hills would render it easy for a small party to coop up the garrison. But as an enemy would always endeavour to approach unseen, and to prevent the country from being alarmed, these stations would undoubtedly be objects of attack; and hence we should be warranted in supposing that they were to a certain extent fortified, even were the appearance of ramparts less unequivocal." Now, as Sir George advocates the opinion that vitrification was an accidental result of fires being kindled in these forts, of what possible use could they be as strongholds? For if these watch-towers were lit when the enemy appeared, then of course those within would be compelled to evacuate them, as no living thing could have breathed within some hundred feet of the place where such immense conflagrations took place. It seems, therefore, a very improbable circumstance, that men, even allowing that they were sunk in the lowest barbarism, would laboriously construct and fortify a place which they must have been aware it would be necessary to abandon at the very time when they were most needed.

With regard to the vitrification on the hill called the Top of Noth, the same writer observes: "The vitrification is only in the inside, which is a very satisfactory confirmation of the idea that it has been produced by signal-fires. Had the outside of the rampart on Top of Noth[1] been vitrified, we might have been warranted in concluding that fire had been used to strengthen it. Had the inside been vitrified with this view, it is impossible to conceive that no attempt was made to cement the outside also; since in every structure for defence, however rude, we find the strongest, and not, as in this instance, the weakest, part opposed to the approach of an enemy." This reasoning seems by no means conclusive. Vitrification was had recourse to, not because the vitrified matter thus formed was of a stronger nature than the materials which it bound together, but simply because it did bind or cement them, so as to form one solid fabric. Now this might be accomplished either on the one side or the other, without making any very great difference as to strength. It is, however, very problematical if those who constructed these fabrics had any thing of this kind in view when they erected them; and as vitrification occurs on the outside of other forts, little weight can be attached to this argument. In those forts which were vitrified only on the inside, it seems probable, that from the nature of the hill where they stood, it was found impracticable to accomplish it on the outside. Various other circumstances besides the nature of the ground may have occurred to determine both the extent of the vitrification and the choice of the parts where it was to be effected.

Sir George Mackenzie further observes, with respect to the situation of the forts: "We do not remember an instance in which there is not much higher ground immediately contiguous to the hills on which the vitrifications are found."[2] Now, granting that the situation of every one of them was a commanding one, and that the whole were connected together like links in a chain, so that a fire on any given hill could readily communicate intelligence to the others, is it not probable that those who

---

[1] Other individuals, who have examined the above fort, inform us that it is vitrified on the outside as much as on the inside.

[2] There is no high ground contiguous to Dunadeer or to Noth.

erected the signal-stations would have chosen the highest accessible elevations, such as towered above all the neighbouring heights, and commanded the widest range of country? By this means the end would not only have been more perfectly effected, but the number of signal-stations would have been lessened by one half, or perhaps more; and to suppose that the aboriginal inhabitants of Scotland would have overlooked this obvious fact, is to attribute to them a degree of ignorance below that of the most savage tribes which the enterprise of modern times has discovered. An erroneous notion seems to prevail as to the extent of fire requisite to convey intelligence of the approach of a foe. But it was not necessary to keep up the combustion for any length of time. Supposing that these were signal-stations, a temporary blaze would communicate all the intelligence that was required, and just as much as could have been conveyed, although the fire had been continued for a considerable period of time. The more that the advocates of the beacon theory insist on their being a regular chain of forts, the less necessity there is for supposing that the fires were so large, and continued for such a length of time, as to vitrify rocks. If it be urged, as it has been, that vitrification was produced, not by the intensity of the fire at one time, but resulted from repeated applications of it, still this could only apply to vitrification upon the surface; for, allowing that on any given occasion, when the beacon was lighted, the heat was sufficient to vitrify the rocks one inch inwards, upon the next occasion when it became necessary to repeat the signal in the same place, it is not to be supposed that it would vitrify it another inch farther inwards. This supposition would involve the absurdity that the fires lighted were on every successive occasion stronger and stronger, a circumstance which was not likely to occur. Besides, considering the height to which it was necessary to convey the combustibles, it is probable that, when the fires were once found to answer the purpose, and the people knew that they would do so again, they would become less rather than greater. Hence we may conclude, that in every case where the vitrification penetrates to some depth inwards, it resulted from an intense *continuous* heat, kept up for a long period, not from a series of petty fires. Where *the chain of communication was regular*, there was, as we have said, no necessity for such stupendous piles of burning wood as were requisite for vitrifying some feet of a wall; the combustion of a few trees would have accomplished the end as well as if the blaze of Ætna had irradiated the summits of the hills. But though not an absolute necessity, there was a degree of propriety which could scarcely have been overlooked in placing them within sight of each other, as has been asserted by the advocates of the beacon theory. Dr Macculloch, however, as we have seen, has denied that this is the case; but his statement must be taken with caution, for a great many sites probably remain undiscovered. However, the main question will not be affected by the decision of this point. The more numerous the forts were, the less use was there for immense conflagrations, and hence the probability is lessened that they were so extensive as to fuse masses of rock.

The following is a quotation from one of the papers of Dr Hibbert: "None of these vitrified forts exhibit, as from many writers we should be erroneously led to suppose, any regular masonry in their structure. Unhewn fragments of stones, and water-worn boulders, sometimes mingled with smaller gravel, appear in a quantity almost exceeding belief, following the contour of the summit of a mountain, or, as in the instance of a fort which is situated in the Kyles of Bute, following the contour of a small holm or islet, elevated a few yards only above the level of the sea; and in cases where, owing to the more exposed nature of the ground, a stronger defence is demanded, a double or even treble rampart of the same rude materials is added. The vitrification which characterizes these forts is, in some few of them, displayed to an extent that is perfectly astonishing; while in other instances it is with difficulty to be detected."

At an early period, the want of proper tools for either quarrying stones, or hewing them into symmetrical forms, would compel builders to seize upon such masses as presented themselves, whether round, oval, or of any other shape. Now, in order to form a level bed upon which these might repose with any degree of security, they would naturally have recourse to gravel and debris of some kind, for at this period they seem to have been ignorant of cement. It cannot be denied that a very unstable erection would result from this method of building; for the walls would not only be easily demolished by a hostile force, but rain, which falls in large quantities in mountainous regions, by percolating through the fissures, would soon have washed away the unconsolidated mass. But, granting that signal-fires had accidentally vitrified the walls in one instance, is it not to be presumed that the idea of cementing the walls of their strongholds by means of fire would suggest itself to those who observed the fact? This is an extremely probable circumstance; and it is strongly corroborated by the fact mentioned by Dr Macculloch, and many others who have examined these ruins, that stones of an easily fusible nature were brought from some distance, whilst those composing the mountain upon which they stood were neglected. This was certainly done intentionally; but of what use was it to build of such materials the walls of what may be called a furnace? Obviously of none whatever. On the contrary, there was an evident disadvantage. For as in every fire-place a plentiful supply of air is necessary to support combustion, it is clear, that as soon as the rocks began to melt, the interstices would have been filled up, and the combustion immediately checked. It was the object of the builders to construct their fire-places of unfusible rocks, and it was also necessary to leave numerous openings for the free admission of air; but it would appear that no indication of any such thing is to be traced in these ruins, a circumstance which strongly supports the truth of the hypothesis that they were regular forts, not beacon-stations. The presence of wells or tanks for water in some of these forts, of double and of triple walls and causeways leading up to them in others, besides many other circumstances which might be adduced, all go to prove the same view.

In a word, the probability is, that the natives having observed the effects of fire upon some stones of ramparts which enclosed beacon-fires, acquired the idea of consolidating their places of strength by the same means, at a time when the use of cement was unknown. Those parts of vitrified forts which show that mortar was used in their construction must, according to all accounts, be referred to a later date than that of the vitrified portions of these fabrics. (R. R. R.)

FORT AUGUSTUS, the central fort of three such establishments erected for the purpose of overawing the Highlands since the Revolution. It is situated in the centre of a beautiful plain or opening in the hills, in the heart of Inverness-shire, at the western extremity of Lochness, and on the south bank of the Caledonian Canal. Fort Augustus is the weakest of the three forts mentioned, and was easily taken and destroyed by the Highland insurgents during the revolt of 1745. It resembles a gentleman's house more than a place of military strength; and, though capable of containing 400 soldiers, is now sufficiently garrisoned by a few veteran artillerymen.

FORT GEORGE, a fortress of Scotland, in the county of Inverness. It is an irregular polygon of six bastions, mounted with eighty pieces of cannon, and is situated on the southern extremity of a low peninsula which projects into the Murray Firth, about twelve miles north-east of Inverness. The whole fortress covers an area of ten Scotch acres, and the barracks possess accommodation for about 3000 troops. This fortress was begun in 1746, and completed in 1764, at an expense of L.160,000. It was constructed with the intention of keeping the Highlands in check; but for this purpose it is now no longer required, and only serves as a barrack for soldiers. It is usually occupied by a governor, lieutenant-governor, several inferior officers, and one or two companies of soldiers. The view from the ramparts is extensive and varied.

FORT ST DAVID, a town of Hindustan, on the sea-coast of the Carnatic, situated on the river Tripapolore. Three rivers of considerable size all fall into the sea in the space of four miles within the bounds of Fort St David. The Panaur is about 1800 yards to the north of the Tripapolore, and the two streams communicate by a canal which runs parallel to the margin of the sea, from which it is distant about 1000 yards. Fort St David stands in the angle formed by the junction of the canal with the Tripapolore, which passes close to the site of the fort, and then sends to the south an arm that joins at no great distance the river of Bandapollam, where both in one channel continue along the eastern side of Cuddalore, separated from the sea by a mound of sand. This factory was first established in the year 1691. After the capture of Madras by the French in 1746, the English were besieged here without success; and from this period it continued the head of the English settlements till 1758, when it was taken by Lally, after a short siege, and the fortifications destroyed. It is 100 miles south-south-west from Madras, and 15 south-south-west from Pondicherry. Long. 79. 57. E. Lat. 11. 46. N.

FORT WILLIAM, a fortress of Scotland, in the county of Inverness. It is situated on the east side of Lochiel, and the south side of the small river Nevis, where it falls into that inlet of the sea, at the distance of sixty-one miles south-west of Inverness, and twenty-nine and a half south-west of Fort Augustus. It is of a triangular form, with two bastions mounting fifteen twelve-pounders. The fort was originally built during the usurpation of Cromwell, by General Monk, and occupied much more ground at that time than it does at present. During the reign of William III. it was rebuilt on a smaller scale, and received its name in honour of that monarch. In the year 1745 it stood successfully a siege of five weeks, but is by no means a place of great strength. It is now garrisoned by a governor, fort-major, and a company of soldiers.

FORTALICE, in *Scotch Law*, signified anciently a small place of strength, built for the defence of the country, and which on that account was formerly reckoned *inter regalia*, and did not go along with the lands upon which it was situated without a special grant from the crown. Now, fortalices are carried by a general grant of the lands; and the word has become synonymous with manor-place, messuage, and the like.

FORTAVENTURA, or FUERTEVENTURA, one of the Canary Islands. It is fertile in corn and excellent fruits, and remarkable for its numerous breed of goats and prodigious quantity of goat-milk cheese. For its size and population see the article CANARY ISLANDS.

FORTESCUE, SIR JOHN, an eminent English lawyer in the reign of Henry VI. was descended from an ancient family in Devonshire, though both the time and place of his birth are unknown. He is supposed to have been educated at Oxford, and the great learning displayed in his writings does no discredit to such a supposition; but it is nevertheless altogether uncertain at which university he studied, or whether he ever studied at any. When he turned his views to the legal profession he entered himself of Lincoln's Inn, where he soon distinguished himself by his knowledge of the civil as well as of the common law. In the fourth year of Henry VI. he was appointed one of the governors of Lincoln's Inn, and three years afterwards the same office was again conferred upon him. In 1441 he was made a king's serjeant at law, and the following year chief justice of the King's Bench. As a judge Fortescue is highly commended for his wisdom, gravity, and uprightness; and he seems to have enjoyed great favour with the king, who is said to have given him some substantial proofs of esteem and regard. He held his office during the remainder of the reign of Henry VI. to whom he steadily adhered; and having faithfully served that unfortunate monarch in all his troubles, he was attainted of treason in the first parliament of Edward VI. which assembled at Westminster in November 1461, having been included in the same act by which Henry VI., Margaret of Anjou his queen, Edward their son, and many persons of the first distinction, were likewise attainted. When Henry subsequently fled into Scotland, he is supposed to have appointed Fortescue, who appears to have accompanied him in his flight, chancellor of England; and although the name of the latter is not found recorded in the patent rolls, because, as Selden remarks, "being with Henry VI. driven into Scotland by the fortune of the wars with the house of York, he was made chancellor of England while he was there," yet several writers have mentioned him by this style and title; and in his book *De Laudibus Legum Angliæ*, he calls himself *Cancellarius Angliæ*, which seems to settle the question. Early in 1463, Fortescue embarked at Bamburg with Queen Margaret, Prince Edward her son, and many other persons of distinction who followed the fortunes of the house of Lancaster, and landed at Helvoetsluys, from which the party were conducted by Bruges and Lisle to Lorraine. Being thus expatriated, he remained many years on the Continent, moving about from place to place, as the necessities of the royal exiles required, and endeavouring to promote their interest by every means in his power. But his most important labours during this period were of a different and more lasting kind. Having observed that Prince Edward applied himself wholly to military exercises, and seemed to think of nothing but qualifying himself to command in battle, Fortescue, who had observed in him indications of a sound understanding, judged it high time to endeavour to give him other impressions, and particularly to infuse into his mind just notions of the constitution of his country, as well as a due regard for its laws. With this view he drew up his celebrated work *De Laudibus Legum Angliæ*, which, though it failed of its primary intention, owing to the barbarous murder of the young prince, for whose benefit it was composed, will yet remain a lasting monument of the author's learning and patriotism. When the prospects of the exiles began to brighten a little, the queen and the prince returned to England, accompanied by Fortescue and others, who no doubt hoped that a more auspicious day was about to dawn upon the descendant of time-honoured Lancaster. But destiny still counter-worked the designs of the heroic Margaret. Her attempt to assert the rights of her son totally failed; and the chancellor, forced to reconcile himself as he best could to the victorious Edward IV. wrote an apology for his conduct, which, though Selden had seen it, has never been published. Little further is known respecting the life of this remarkable man, excepting that, amidst all the changes of masters and varieties of fortune, he stedfastly maintained those constitutional principles which he had with equal ability and conciseness explained in the celebrated treatise above referred to. He appears to have died at a very advanced age, though the time of his death, like the date of his birth, has not been ascertained.

Fortescue's masterly vindication of the laws of England, though received with great favour by the learned of the profession to whom it was communicated, did not appear in print until the reign of Henry VIII. when it was published by Whitechurch in 16mo, but without a date. In 1516 it was translated by Mulcaster, and printed by Tottel; and again in 1567, 1573, and 1575, and also by White in 1598, 1599, and 1609. It was likewise printed, with Hengham's *Summa Magna et Parva*, in 1616 and 1660, 12mo; and again with Selden's notes in 1672, in 12mo. In 1737 it appeared in folio; and, in 1775, an English translation, with the original Latin, and Selden's notes, besides a variety of remarks relative to the history, antiquities, and laws of England, was published in 8vo. Waterhouse's *Fortescue Illustratus*, which appeared in 1663, though prolix and defective in style, may be consulted with advantage, and will serve to facilitate the labours of more judicious and able inquirers. 2. Another valuable and learned work by the same author, but written in English, was published in the reign of Queen Anne, under the title of The Difference between an absolute and limited Monarchy, as it more particularly regards the English Constitution, and accompanied with some remarks by John Fortescue Aland of the Inner Temple, London, 1714, in 8vo; and a second edition with amendments appeared in 1719, 8vo. In the Cotton Library there is a manuscript of this work, in the title of which it is said to have been addressed to Henry VI.; but many passages show plainly that it was written in favour of Edward IV. 3. Of the author's other writings, which were pretty numerous, but never printed, we know nothing more than can be collected from the titles, and the commendations bestowed on them by persons who had perused the manuscripts. Those still extant are, 1. *Opusculum de Natura Legis Naturæ, et de ejus censura in successione Regnorum Supremorum*; 2. *Defensio juris Domus Lancastriæ*; 3. Genealogy of the House of Lancaster; 4. Of the Title of the House of York; 5. *Genealogiæ Regum Scotiæ*; 6. A Dialogue between Understanding and Faith; 7. A Prayer Book which savours much of the Times we live in; with some others, which, as the author was a man of great knowledge and observation, will, we trust, yet be printed. When lord-chancellor, Fortescue is said to have drawn up the statute of the 28th Henry VI. on the resumption of certain grants of the crown, which, though much relied on by writers on that subject, is not extant in any edition of the statutes. (A.)

FORTH is the name of the largest river in Scotland. It is first formed of several smaller streams, rising on the north of Ben-Lomond, or flowing from the lakes in the adjacent country. It proceeds easterly in a direct course for above a hundred miles, receiving in its progress the tributary waters of the Goodie, the Teith, and the Allan, above Stirling, and below it the Devon, the Carron, the Avon, the Almond, the Leith, the Esk, the Leven, the Tyne, and others; and it discharges itself into the German Ocean in about 56° 10′ of north latitude. The windings of the river both above and below Stirling are particularly beautiful. The windings above Stirling to Gartmore extend about thirty-three miles in length, though only twenty in a direct line; and towards Alloa the river flows for twenty-four miles in a tortuous course, without advancing more in a straight line than six. Its width at Borrowstownness is four miles, at Queensferry two, at Kinghorn nearly six, between Dysart and Aberlady about twelve, between Elie and Dirleton Common eight, and between St Abb's Head and Fifeness, where the Forth joins the German Ocean, its breadth is from thirty-five to forty miles.

It is so deep as to be navigable by vessels of seventy tons burden as high up as Stirling, and the tide flows a mile above that town. At low water, above Borrowstownness, it seldom exceeds two fathoms in depth; at Queensferry, between Inchgarvey and the north shore, it deepens to thirty-seven fathoms. It becomes shallower again where it widens, till it reaches the north channel between Kinghorn-ness and Inchkeith, where it deepens to twenty-six fathoms. Between Elie and the south shore its depth is sometimes thirty fathoms; and it never exceeds this depth to the westward of its junction with the German Ocean.

The Forth, like other streams connected with the ocean, ebbs and flows twice in twenty-four hours; but the flood and ebb run about two hours longer in the middle than at the shore. It was high water, full and change, according to Captain Thomas, in 1815, at

	H.	M.		Spring Tides, Rise.	Neap Tides, Rise.
Ely Harbour,............	2	11	P. M.	14 feet.	6 feet.
Leith and Burntisland,	2	15		16½	7
At Hopetoun House....	2	30		17	6½

The tides at Leith and Kinghorn rise sometimes as high as nineteen feet above low-water mark, the average being seventeen and a half feet.

There are in the Forth, as elsewhere in similar rivers and arms of the sea, particular currents. Amongst the most remarkable are those known by the name of *leakies*, above Queensferry, and which are particularly observed from Culross to Alloa. These consist in an intermission of the tide at certain places, during the flood at others, and before high water at certain places, the sea ebbing at others; and also whilst the sea ebbs at certain places, and before low water, the ebb intermitting at others, and a flow commencing and continuing some time, after which the ebbing is resumed until low water. This is observable during two hours, and the irregularity occupies more of the river, according as it is spring or neap tides.

Certain winds, acting upon the great mass of the Atlantic Ocean, affect the times at which it is high or low water in the Forth, while their effect upon the extent of the rise or fall of its waters is frequently very considerable.

The prevailing winds of the Forth will be seen by the following table, constructed from observations taken every day at ten o'clock forenoon, on the island of Inchkeith, for the ten successive years ending on 31st December 1826.

Direction of the Winds.	Description of the Winds.				
	Light Airs.	Breezes.	Gales.	Storms.	Total.
South..............	96	165	29	2	292

	1090	1971	503	88	3652

Nearly the same facts are better brought out by the following table, constructed from the observations taken every day, in the Calton Hill observatory, under the superintendence of the astronomical observer, for the same ten years, ending on the 31st December 1826. The entry in the register for each day is applicable to the winds of its whole twenty-four hours.

Direction of the Winds.	Description of the Winds.						
	Moderate and Calm.	Brisk.	Sharp.	High.	Very High.	Extremely High.	Total.
South	85	2	...	17	3	4	111
South-west	310	43	1	178	68	30	630
West	444	54	3	235	54	8	798
North-west	207	33	4	143	48	9	444
North	61	6	4	17	5	...	93
North-east	122	11	2	21	2	...	158
East	381	37	4	45	4	...	471
South-east	131	8	3	14	2	...	158
Changeable	588	44	4	119	29	5	789
	2329	238	25	789	215	56	3652

From these tables it will be observed, that the prevailing winds in the Forth, the gales and storms at Inchkeith, and the very high and extremely high winds at the Calton Hill observatory, chiefly proceed from westerly directions.

The waters of the Forth and its tributary streams are all fresh until they mingle with that of the ocean. Long before the river becomes two miles wide, they acquire a saltness which differs little, if at all, from that of the sea in general. The water in the neighbourhood of the coal-works of the Forth has been often evaporated for the sake of the salt, which was here at one time an extensive article of manufacture.

The constituent parts of 10,000 parts of the waters of the Frith were found by Mr Murray,[1] in the course of three different analyses made in different ways, to contain,

Muriate of soda	242·51	245·04	220·01
Sulphate of magnesia	7·86	17·04	...
Sulphate of soda	9·99	2·66	33·16
Muriate of magnesia	34·49	28·63	42·08
Muriate of lime	...	...	7·84
Sulphate of lime	9·45	9·72	...
	304·30	303·09	303·09

Mr Murray placed most confidence in the results obtained from the last of these analyses.

The minerals of which the banks of the Forth are composed will be found described under the counties of East-Lothian, Mid-Lothian, West-Lothian, Stirling, Clackmannan, Perth, and Fife, by all which the Forth is bounded.

Coal, besides being wrought in these counties, was once worked near Culross and Torryburn, under the bed of the river, and partly by pits within high-water mark. At the mouths of these pits there were piers, at which vessels were loaded with the coals. But these mines have been for many years filled with water.

The bed of this river consists to a great extent of mud, and in many places the freestone bottom is covered with it to the depth of twenty feet. Its banks above Alloa, and a great way below that place, are formed of this material, which is brought down by the waters from the higher levels; and the carses of Stirling and Falkirk, &c. which have been formed from its accumulation, are secured at their lowest levels by sea-dikes against inundations, occasioned by the rise of the tides.

The recent alluvial cover to the westward of Alloa has been found by Mr Bald in some places to be no less than ninety feet deep, and to contain trunks and branches of large trees, and beds of sand with sea shells, particularly of the oyster, cockle, mussel, donax, &c.; and similar beds of shells not only abound at and below Alloa, but are found several miles to the westward of Stirling similarly situated. Many of the oyster-shells are of uncommon thickness, and larger than any specimens that can now be found. What makes the westerly position in which these uncommonly large shells are found very remarkable is, that there are no specimens of the oyster now found farther up the Forth than Queensferry.

There is also a bed of marine shells on the banks of the Forth near Borrowstownness, about three miles in length, and several feet in thickness, and which is situated many feet above the present level of the waters of the Forth. This circumstance would favour the opinion that the sea in this quarter had at one time occupied a higher elevation than at present; an opinion which is further supported by the fact of the skeleton of a large whale having been found some time ago in the lands of Airthrey, near Stirling. The surface of the ground where the remains of this huge marine animal were deposited, was ascertained by Mr Stevenson to be twenty-four feet nine inches above the present level of the Forth at high water of spring tides.

But if the land has been gaining on the waters in the upper part of the Forth, ground has been lost farther down the estuary. The sea has made considerable encroachments at North Berwick; at Newhaven, an arsenal and dock built in the reign of James IV. in the fifteenth century has been swept away; and on the coast of Fife, in 1803, the last remains of the Priory of Crail, and the ground on which it stood, met with a similar fate.

At Largo Bay the sea seems now to be covering ground which was formerly dry land. Here a submarine forest has been discovered, the roots of the trees penetrating into a brown clay, over which is irregularly distributed a covering of sand and fine gravel. The peat upon it is composed of land and fresh-water plants, amongst which are hazel nuts, and the remains of birch, hazel, and alder trees. The root of one tree, apparently an alder, was here traced by Dr Fleming to an extent of more than six feet from the trunk.

There is an abundant supply of sea-weed on almost all the shores of the Forth, which has often been burned at various places to form kelp. Within the last twelve or fifteen years this manufacture in the Forth has been entirely given up. The produce of the rocks, or what is cast ashore in storms, is now therefore only used as manure.

---

[1] *Edinburgh Phil. Trans.* viii.

Seals are often seen sitting on the rocks, or swimming along the coasts of the Forth. Sharks are also said to have occasionally made their appearance. Numerous cetacea from twenty to sixty feet long, and grampuses, have often been stranded in the Forth. A male Beluga, or white whale, apparently of full growth, appeared in its waters in 1815. It was killed by the salmon fishers near the abbey of Cambuskenneth, and sent to Edinburgh, where it was dissected by the late Dr Barclay.

Numerous porpoises are often observed tumbling and disporting in the Frith. The salmon is abundant, and salmon fisheries have been established at Stirling, Abercorn, and near Queensferry, &c. Herrings are also plentiful, and at Burntisland and various other stations the fishery is prosecuted successfully. The other fishes caught in the Forth are mackerel, haddock, cod, turbot, skate, flounders, halibut, soles, &c. In fact, fish are so abundant in the Frith, that upwards of forty sail of foreign vessels are said to have been frequently seen fishing on the cod banks opposite St Abb's Head, guarded by a Dutch ship of war. Almost all parts of the Frith are also fished with success by English vessels. Sometimes a dozen at a time of the English fishing smacks are there seen busily employed. One of them alone has been known to catch seventy-two scores of large cod in two days. Taking this as an average, and it is said not to be a high one, these vessels in a week would catch 52,000 of the finest fish, which is a much larger quantity than is believed to be sold in the Edinburgh market during a whole year. This market is chiefly supplied by Newhaven and Fisherrow boatmen, who purchase their fish generally from fishermen residing at a distance upon the coasts of the Frith, many of whom are under contracts with English fishmongers for the supply of the London markets.

Cellardike is one of the principal stations of this fishery in the Forth. It supplies the London market to a great extent with salted cod, and Glasgow as well as Edinburgh with fresh fish; but here, as elsewhere in the Forth, the fishermen migrate for months to the herring fishery in the north of Scotland, at the season when fish is most abundant, particularly the haddock. This interrupts the regular supply of that important article. Lobsters and crabs are also caught at almost all the fishing stations in the Forth. Mussels, cockles, lampits, and wilks, are also collected in great quantities at those places where they abound; and oysters are extensively fished at the oyster-beds, which are met with chiefly to the eastward of Leith.

There is nothing remarkable about the wild fowl resorting to the Forth in winter. The solan geese of the Bass have been already described under that head, to which the reader is referred.

Besides the Bass, there is another island in its neighbourhood, the May; and the larger islands farther up the Forth are Inchkeith, Inchcolm, and Inchgarvey, which will be found described in separate articles. The smaller islands are Fidra, the Lamb, and Craigleith, near the Bass, and Mickry and Cramond Islands near Inchcolm.

The principal sand banks which obstruct the navigation of the Forth are the Drum Sands near Cramond, and the Sandend to the east of Burntisland. The principal rocks which require to be avoided by the mariner are the South Carr reef lying N.N.W. from Dunbar, the North Carr about a mile and a quarter east of Fifeness, the Blea to the west of Kinghorn, the Commons to the west of Burntisland, Craig Waugh S.E. $\frac{1}{2}$ E. of Inchkeith, and the Gunnet Rock, Pallas Rock, Longcraig, Briggs, and Harwit, in its neighbourhood; and several miles farther west, and nearer Inchcolm, the Oxcares, Carcraig, and Mickry Stone.

Many of these rocks are seldom seen at the lowest ebbs; their position, together with the different landmarks which are necessary to point them out to the mariner, are well delineated on an admiralty chart of the Forth by Captain Thomas, of the navy, published in 1815.

To show their position still better, floating buoys have been placed upon Craig Waugh, the Gunnet, the Harwit, and the Pallas rocks, and beacons have been erected on the Oxcares and the North Carr. The last was completed in 1821, with a cast-iron ball formed in ribs, and is elevated upwards of twenty-five feet above the medium level of the sea, the under part of the beacon being a circular building of masonry of eighteen feet in diameter.

Besides these provisions for aiding the navigator, there is a lighthouse on the Isle of May. It has been lighted since the 1st of February 1816, during night, with oil; and, by means of reflectors, gives what is called by mariners a stationary light. Being defended from the weather in a glazed light roof, it has a uniform steady appearance, resembling a star of the first magnitude, and is seen from all points of the compass to the distance of seven leagues. In 1804, another lighthouse was erected on the summit of Inchkeith. Its lanthorn is 229 feet above the level of the sea, of which the building forms forty-five feet. On the 1st of February 1816 it was converted into a revolving light without colour, seen from all points of the compass, and exhibiting a bright light once every minute, and becoming less luminous, till to a distant observer it totally disappears. By this arrangement the possibility of mistaking Inchkeith light for any other of the Forth is effectually prevented. There are also light-houses on the pier-heads of Leith, Newhaven, Burntisland, Pettycur, Queensferry, &c. on which, whilst there is water in the harbours during night, care is taken to keep the lamps burning.

The harbours and landing places are, on the south side of the Forth, Dunbar, North Berwick, Port-Seton, Morison's Haven, Fisherrow, Leith, Newhaven, Trinity, Queensferry, Borrowstownness, and Grangemouth; and on the north side, Crail, Anstruther, Elie, Pittenweem, Leven, Methel, West Wemyss, Dysart, Kirkaldy, Kinghorn, Pettycur, Burntisland, Starleyburn, Aberdour, St Davids, Inverkeithing, Queensferry, Charleston, Crombie Point, Culross, Kincardine, and Alloa. The more important of these harbours and landing places will be found described in separate articles. The anchorage in the Forth is in general good, and in particular the anchorage at Aberlady Bay, in the westerly part of Largo Bay, and in the roads of Burntisland, Leith, St Davids, Limekilns, &c.

The coasting and foreign trade of the Frith is carried on in vessels varying in size from eighteen tons to nearly 500. The principal port to which they belong is Leith; but there are several whalers and vessels engaged in the Australian, American, Mediterranean, and Baltic trades, belonging to other ports in the Forth.

The traffic in goods and passengers between the ports in the Forth and London, Greenock, Glasgow, Liverpool, Hull, Newcastle, Dundee, Perth, Aberdeen, Inverness, Peterhead, and almost every considerable town in Scotland, is conducted chiefly by the vessels of joint-stock companies, which vessels sail periodically. A joint-stock company is also engaged in the Leith, Hamburg, and Rotterdam trades, the vessels belonging to which sail at present from Leith every alternate Tuesday. The Glasgow, Greenock, and Liverpool trade is chiefly conducted through the Forth and Clyde Canal; as to which, see NAVIGATION, *Inland*, and GRANGEMOUTH.

The names of all the vessels belonging to the Forth are registered in the custom-houses of Leith, Borrowstownness, Kirkaldy, and Anstruther. The aggregate tonnage registered at each of these ports will be found under the articles KIRKALDY and LEITH, together with a statement of the number of arrivals in a year from foreign ports and coastwise, and the chief goods and other articles landed and exported, with the aggregate duties paid upon them.

To facilitate the intercourse between the northern and southern parts of Scotland by a communication across the river Forth, wooden bridges near Stirling were erected at a very early period. The time at which the present old bridge of Stirling was erected is unknown; but it must have been built before the year 1571, as Archbishop Hamilton is then said to have been hanged over it by the king's faction under the Regent Lennox. The newest bridge at Stirling is of very recent erection. There was, within the last thirty years, a project of erecting a suspension bridge at Queensferry, and another project of making a tunnel near the same place; but the practicability of these schemes has been doubted.

From the want of such facilities of passage across the Forth, the regulation of its ferries became the object of legislative enactments at so early a period as the year 1467. Before the introduction of steam navigation, the traffic at these ferries was chiefly conducted by open boats, pinnaces, and yawls of various sizes; and from the want of low-water piers, they seldom departed from either side except at high water. Although by the statute 1686 all Scotch ferries were subjected to the regulation of the justices of the peace and commissioners of supply, the traffic on the Forth at all times received much interruption from not having stationary superintendents, and the consequent want of proper subordination.

Most of the ferries on the Forth are still private property. The private rights to the Queensferry passage were in 1809 purchased by parliamentary trustees, for upwards of L.8550; and these trustees, out of funds arising from a government grant, at first of L.13,525, and it is believed afterwards of L.2300, and loans from private individuals to as great an extent upon the security of the profits arising from the traffic, have improved the landing places, and purchased and continue to maintain suitable vessels. In 1828, the debts of this trust to banks and private individuals, with interest, amounted to L.16,410. 2s. 1d.

The rent payable by the tacksmen of the ferry, including an allowance of L.200 a year from the post-office, was then	L.1920	0	0
The expenditure, consisting of repairs on piers, vessels, feu-duties, interest of debts, and officers' salaries, &c. then amounted to	1615	9	0
Leaving a surplus of	L.304	11	0

The annual surplus since 1828 is understood to be rather greater than this, in consequence of the piers requiring but little repair. The amount of the traffic in 1833 was estimated at 6180 carriages and carts, 11,750 horses, 16,500 cattle, 27,000 sheep and lambs, 4500 barrel-bulk of luggage, 73,500 passengers, including 500 paupers allowed to pass gratis, and 3000 Highland shearers, and exclusive of mail guards and coachmen twice every day, and of military baggage and stores having a free passage. The number of passengers landed from, or taken off to, steam vessels passing up and down the Frith, at Queensferry, is estimated at not less than 4000.

The ferry stations of Burntisland and Newhaven were added in 1792 to the stations of Kinghorn and Leith, which had been used for the great ferry of the Forth from the very earliest period of our history; and by the act 32 Geo. III. cap. 93, the traffic in goods and passengers crossing the Forth between these stations was placed under the superintendence of trustees, with powers to raise tolls for the improvement of the harbours. These trustees obtained further powers from parliament in 1813 to purchase from the boatmen the vessels used upon these ferries, and to carry on the trade themselves exclusively both as to goods and passengers. In 1813 and 1821 they were further empowered by parliament to acquire rights to extend their monopoly in transporting passengers between Mid-Lothian, and Kirkaldy and Dysart on the opposite coast. They have tried both; but some years ago they abandoned the Dysart passage. By a loan from government to the extent of L.10,000, and from private individuals of L.19,516. 13s. 4d., besides a sum from the Navy Board, they have erected a stone pier at Newhaven, made small repairs, and added landing slips to the harbours on the north side; and they conduct the ferry to Leith at present by means of sailing vessels; and between Newhaven on the one side, and Burntisland, Kinghorn, and Kirkaldy, on the other, by steam navigation, their vessels making from three to four trips to and from each of these ports daily.

In 1832 the gross debts of this trust, with interest, amounted to	L.39,494	7	2½
Deduct their property in boats, stores, fixtures, &c. and their funds, valued at	16,081	7	6
Nett debt	L.23,412	19	8½

The revenue of the steam-vessel ferry to and from Newhaven in 1832 was	L.6,995	7	8½
Ditto of the sail-boat ferry at Leith, and Burntisland, and Kinghorn, for passengers, cattle, and goods, landed there	1,051	2	7½
Ditto of cutters and yauls, &c.	7	5	6
Royalty for Newhaven pier L.238. 14s. 2d. interest on bank accounts, towing vessels out of harbours, light-house revenue, &c.	401	13	5½
	L.8,455	9	3½

The steam-vessels' expenses in 1832 were	L.5,228	15	0½
Sail-boat expenses	1,077	2	11½
General charges of management, repairs on houses, and piers, light-houses, &c.	504	12	9
	L.6,810	10	9
Interest of loans	955	16	8
Allowance for deterioration of vessels by wear and tear	490	0	0
Total expenditure	L.8,256	7	5

From this statement there would appear to be a surplus revenue of L.199. 1s. 10½d. This arises from the steam navigation. The Leith ferry appears to be conducted at a dead loss.

The number of passages and passengers to and from Newhaven in 1832 was as follows:

	Passages.	Paying Passengers.	Free.	
			Military.	Poor.
At the ferries of				
Burntisland	2,363	19,898	80	58
Kinghorn	1,668	31,312	56	71
Kirkaldy	1,536	29,134	284	111
Total	5,567	80,344	420	240
At the ferries between				
Leith and Kinghorn	1,052	1,296		
Leith and Burntisland	631	858		
	1,683	2,154		

The revenue arising at the Burntisland and Leith ferry in 1832 from cattle and carriages was L.15. 18s. 1d., and from goods L.435. 17s. 8d. The revenue arising at the Leith and Kinghorn ferry during the same period from cattle and carriages was L.126. 7s. 6½d., and from goods L.363. 16s. 4d.

The revenue arising from the carriage of goods at the ferry between Leith and Kirkaldy is not known, as it is conducted by private traders, and is not within the limits of the trustees' monopoly. As little is generally known concerning the numbers of the passengers crossing in the steam-vessels which now regularly ply to and from Dysart, Largo, Queensferry, Cromby Point, Limekilns, Alloa, Stirling, Borrowstownness, &c. These vessels land and take in passengers regularly at the low-water Chain Pier at Trinity, which is a noble specimen of what may be done in the erection of useful works by private individuals for the benefit of the public.

The principal projects at present in contemplation for the improvement of these ferries, and in general for extending the navigation of the Forth, are the erection of low-water piers on both sides of the Frith.

Mr Telford, in October 1828, reported to government that it would cost L.38,660. 17s. 2d. to construct a low-water landing place at Newhaven in connection with the ferry pier, so as to secure a depth of water there of ten feet at low water; and that in proceeding farther westward he could not perceive that any advantages were to be obtained.

Another project, founded on a report by Mr Matheson, civil engineer, was to erect at Wardie Point, the property of Captain Donaldson Boswall, a complete landing place and a wet dock. At this place it is stated that at the distance of 1500 feet from the shore there is ten feet deep water at the lowest ebb of stream tides; but the accuracy of the statement has been questioned. The estimated expense of this proposed harbour and other structures is L.122,149.

A third project is that of a joint-stock company to erect at Trinity, to the east of Wardie, and nearer the Ferry Trustees' pier, including the ground whereon the chain pier now stands, a wet dock containing forty-three acres, and affording wharfage to the extent of 12,000 feet. It is proposed that the dock should be entered by a lock 200 feet in length and fifty-five in width, of sufficient dimensions to admit a ship of the line or steam-vessels of the first class. The entrance is meant to be protected by a breakwater 1100 feet long, parallel to the channel of the Frith, which, with two check piers built on arches, would secure an outer harbour 900 feet long by 300 wide, where there would be a low-water landing place; the depth of the water in the outer harbour at the lowest ebbs would be upwards of eleven feet, and twenty-nine feet at high water, and the depth over the whole dock would be only one foot less. The estimated expense of erecting these works, purchasing the grounds, &c. is stated to be L.250,000. Application has been made to parliament for power to carry this project into execution.

A fourth project is that of his grace the Duke of Buccleuch, who, with a munificence seldom displayed by a single individual, has come forward with a proposal to construct at his own expense a deep-water harbour on his property at Granton. This situation is about three quarters of a mile west from the Trinity Chain Pier, in a small bay formed by Granton Point on the west and Wardie Point on the east. Here a depth of twelve feet of water is obtained at low water of spring tides, at the distance of 550 yards from high-water mark, the rise of the tide giving twenty-eight feet at high water of spring tides. It is proposed to extend two piers of masonry to this depth, including between them an area of thirty-five acres, which will be occupied as an outer harbour or receiving basin, and capable of accommodating his majesty's ships of war as well as the largest class of merchant vessels. To the landward of this basin it is proposed to construct a suite of wet docks, to such an extent as may afterwards be found necessary. It is calculated that the expense of each of the piers will be from L.80,000 to L.90,000, and that the wet docks will cost at least L.100,000 more.

The erection of low-water piers on the south side of the Forth, at any of the stations above referred to, should only take place if it be found to be utterly impracticable, by a capacious tide basin, or otherwise, to deepen the harbour of Leith, or secure at that station a sufficient depth of water at the lowest ebbs. At the same time the erection of low-water landing places on both sides of the Forth is now considered by every body as an object of the greatest national importance; and when the relative merits of new grants out of the public funds for such works in distant colonies, or nearer home, come to be considered, it is to be hoped that the harbours on the Forth will receive proper aid from the government, and not be left to be improved exclusively by the enterprise and at the risk of private individuals.

On the north side of the Forth Mr Rennie had advised an extension of the present piers of Burntisland for a low-water landing place there. But Mr Telford recommended to government the construction of a landing pier a little to the eastward; the pier to be at the distance of 700 feet from high water, and carried in to ten feet depth of water at low water of spring tides. He estimates the expense at L.20,801. 9s. 3d. He also recommends a continuation of the road partially made along the beach from the eastward of Burntisland, so as gradually to rise from the eastern extremity of that parish to the town of Kinghorn. But in the event of Kinghorn being preferred as the better of the two stations on the Fife side for a low-water harbour, Mr Telford also reported to government that he would propose to form a very capacious harbour in the bay of Kinghorn, by making an insulated break-water, and a smaller one connected with the Kinghorn Kirk Craig, having an opening between them, and a main landing pier slip on the western side of the harbour. He estimates the expense at L.60,917. 3s.

Another survey and report was obtained at the same time from Mr Buchanan, civil engineer. Mr Buchanan reported that a pier of solid masonry might be carried out 1200 feet on the ridge of rocks stretching from the Kirk Craig, so as to form a harbour which would command a depth of water at the entrance of ten or eleven feet at the lowest spring tides, and of twenty-six feet at high water of ordinary spring tides. This would inclose a space of twenty imperial acres in extent, secure from every storm. He estimates the expense at L.20,159. 14s., and the expense of a level road from it to Kirkaldy, the great seat of the traffic, at L.3960, and that of a railway upon it to the same place at L.2760. 15s. Indeed, the roads to Burntisland and Kirkaldy, referred to in both Mr Telford's and Mr Buchanan's reports, are admitted to be indispensable at whatever station proper landing places are erected.

FORTIFICATION.

Fortification is the art of putting a town or place in such a posture of defence as may enable a comparatively small number of men within to resist, for a certain period of time, the attacks of a numerous army without; or it may be more simply defined the art of putting a place in a state to resist the attack of an enemy.

Fortification may be divided into *Permanent*, or such works as are built round towns, and intended to remain; *Field*, or such as are only required to last for a battle or a campaign; *Defensive*, or the means of resisting attacks; and *Offensive*, or the various modes of attacking fortified places. And these may again be divided into *Regular* and *Irregular*, *Natural* and *Artificial*. Regular fortification is that which is constructed, according to the rules of art, on a figure or polygon which is regular, and has all its sides and angles equal. Irregular fortification, on the contrary, is that where the sides and angles are not uniform, equidistant, or equal, owing to the accidents of the ground, valleys, rivers, and the like. Natural fortification is the strength or capability of defence which nature herself has afforded to particular places by reason of their elevated situations and the difficulties of approaching them; as in the case of high and nearly inaccessible hills, steep rocks, morasses, and the like. Artificial fortification, on the other hand, consists of works so contrived and constructed as to increase the natural advantages of a situation, or to remedy its defects.

INTRODUCTION.

Fortification is very nearly as ancient as the existence of society. When men first assembled together for the purpose of mutual protection, and placed their habitations on the same spot, the law of necessity, springing in this case out of the principle of self-defence, rendered it indispensable for them to adopt some means for securing their families and their property against the sudden inroads of enemies. Hence, when Cain, the son of Adam, built a city, he surrounded it with a wall; and, in like manner, the Babylonians, when they built cities soon after the Deluge, encompassed them with similar defences. In the early ages, men considered themselves as sufficiently protected by a single wall, from behind which they could with safety discharge their darts, arrows, and other missiles, against an assailant. But when, in the progress of improvement, new and more powerful means of attack were discovered, it became necessary to increase, in a corresponding degree, the inert force of resistance; and accordingly the feeble defensive structures of the primitive ages were in time succeeded by solid ramparts, flanked and commanded by elevated towers. In short, as the power of attacking fortresses or places of strength was augmented by successive devices and inventions, the means of resistance were proportionally increased, until the art of fortification arrived at a state of comparative perfection, in which it remained for many ages nearly stationary.

The various improvements which were from time to time made in strengthening the walls, and adding to the defences of ancient cities, are recorded in history, and need not be detailed in this place. The first walls which we read of consisted of brick, the material employed by Cain for the protection of the city which he founded, and called by the name of his son Enoch. Amongst the ancient Greeks, brick and rubble stones intermixed were used for the same purpose, as we find from the description of the wall which connected Mount Hymettus with the city of Athens. The walls of Babylon and Nineveh indicate a prodigious advancement in the art of fortification, and are justly accounted amongst the wonders of the ancient world. Those of the former city, ascribed by some to Belus, and by others to Semiramis, were thirty-two feet in thickness, and a hundred feet in height, surmounted by towers at an average ten feet higher, and cemented by means of bitumen or asphaltum; they encompassed a vast area, and presented a solid defence, which no means of attack known in ancient times were sufficient to overcome or beat down. The walls of Jerusalem, though of smaller dimensions, appear to have been little inferior in strength and solidity to those of Babylon; for, in the siege of that capital by Vespasian, all the Roman battering-rams and other engines, though used with the utmost vigour, required a whole night to disengage four stones in the masonry of the tower of Antonia. But when fortification had arrived at the state in which we find it in the works of these and other cities, it remained stationary for ages, and perhaps even retrograded somewhat, until the discovery of gunpowder, the invention of artillery, and the application of both to military purposes, effected an entire revolution in the principles of attack and defence. Then the round and square towers, which had formed secure flanking defences against assailants armed only with arrows and with darts, afforded no protection against the projectiles discharged by cannon; and even those battlements which had defied the catapult and the battering-ram speedily yielded to the force with which they were now assailed, whilst their defenders were at the same time destroyed, or buried in their ruins.

It being thus found that the ancient system of fortification was of little or no avail against the new method of attack which had been discovered, and which came into general use towards the close of the fifteenth century, it became indispensably necessary to adopt another method of defence. The plan of fortifying with bastions is supposed to have commenced with the Italians early in the fifteenth century. The bastions on the enceinte of Verona, built by the Italian engineer Micheli, in the year 1523, are generally supposed to be the oldest extant; and the next, probably, are those still to be seen at Antwerp, and which were constructed by the Emperor Charles V. in the year 1545. These bastions are small, with narrow gorges and short flanks and faces; and they are placed at a great distance from one another, it being the invariable practice, at the time when they were built, and for a considerable period afterwards, to attack the curtains, and not the faces, of the bastions.

Errard of Bois-le-duc, one of the principal officers of the engineer corps employed by Sully, prime minister of Henri IV. was the first in France who laid down rules respecting the best method of fortifying a place, so as to cover its flank. At the command of the minister, he wrote a book on the subject, which was published in 1594, and in which the details of his method are explained. Errard fortified inwards; and in the square, pentagon, hexagon, heptagon, and octagon, he made the flank perpendicular to the face of the bastion; but in the enneagon, and in all polygons of a greater number of sides, he made it perpendicular to the curtain. In endeavouring to accomplish his object, however, he made the gorges too small, the embrazures too oblique, and left the ditch almost defenceless. This engineer constructed part of the enceinte of the citadel of Doutens, as well as the citadel of Amiens, and also some works at Montreuil and Calais.

The Chevalier Antoine de Ville, who succeeded Errard, published a treatise, dated 1629, in which he completed much that his predecessor had only sketched, and rectified various defects in the method of the latter. The Chevalier was employed under Louis XIII. and constructed new enceintes for Montreuil and Calais. His plan of fortifying has been denominated by some the French method, and by others the Compound System (*Système à trait composé*), because it united the Italian and Spanish methods, from the latter of which it differs only in having no second flanks and fichant lines of defence, and in not confining the flanked or salient angle of the bastion to ninety degrees. The leading maxims of the Chevalier de Ville were, to place the flanks perpendicularly to the curtain, to make them equal to the demigorges, or each equal to a sixth part of the side of the interior polygon, and, in the hexagon and all higher polygons, to confine the flanked angle to ninety degrees. But this plan is liable to nearly the same objections as that of Errard; for here, also, the embrasures are too oblique, especially in the polygons, and the ditch is necessarily but ill defended.

Sixteen years after the publication of De Ville's treatise appeared the work of the Comte de Pagan, which issued from the press in 1645, and contained the development of a system which, in a short time, entirely superseded those of his predecessors. In fact, it was the Comte de Pagan who first disengaged the science of fortification from a number of suppositions which custom had in some measure consecrated, and which, resting more on abstract mathematical reasoning than on practical observation and experience, had hitherto retarded the progress of the art. This engineer acquired great reputation during several sieges which he assisted in conducting under Louis XIII.; but having become blind at the age of thirty-eight, he was obliged to retire from the service, in which he had already obtained the rank of mareschal-de-camp, and he died six years after completing the treatise above mentioned, in which he embodied a full exposition of his system. The Comte de Pagan made the flank perpendicular to the line of defence, in order as much as possible to cover the face of the opposite bastion; and he also pointed out a method of building casemates in a manner peculiar to himself. Vauban borrowed from the Comte de Pagan the length of his perpendicular, and Allain Manesson Mallet, whose construction still remains in favour with many, also proceeded upon the principles laid down by this scientific soldier.[1]

The Mareschal de Vauban was born in 1633; and in 1655, at the time of the Comte de Pagan's death, he had already acquired reputation at several sieges. Vauban followed up the principles suggested by Pagan, and employed them extensively in practice, with consummate skill and judgment. He constructed thirty-three new fortresses, repaired and improved one hundred; and having conducted about fifty sieges, he left his extensive works, and a treatise *De l'Attaque et de la Defense des Places*, published in 1737, to speak for themselves. From the different constructions observable in these works have been compiled the systems which, in the military schools, are denominated Vauban's first, second, and third systems of fortification, and which the reader will find developed in the sequel. Had the genius of Vauban been applied to the discovery of a method for securing a permanent superiority to the defence of fortified places, posterity would have been greatly indebted to him, and even humanity would have had cause to rejoice in such a triumph of military art. But, being engaged in the service of the most ambitious monarch of modern times, Louis XIV. he applied his great talents to forward his master's views, and soon perfected that irresistible system of attack,[2] which has ever since been so successfully followed. Before his time the general superiority was on the side of the defence; but ever since, the case has been so completely reversed, that the success of an attack made with adequate means, and scientifically conducted, is a matter of absolute certainty.

M. Minno Baron de Coehorn, first a general of artillery, then a lieutenant-general of infantry, and ultimately director-general of all the fortified places belonging to the United Provinces of Holland, was the contemporary and rival of Vauban. This able engineer, convinced that, however expensively the rampart of a town may be constructed, it cannot long resist the shock of heavy ordnance, invented three different systems for throwing such obstacles in the way of a besieging force, that, although the place be not thereby rendered impregnable, it can only be approached with great difficulty and hazard. But these methods are only applicable to low and swampy situations, such as are to be found in Holland, and are therefore not available where the localities are of a different or opposite description. At the same time, Bergen-op-Zoom, Manheim, and other places fortified by this engineer, particularly the two former, have very great merit, inasmuch as it is impossible for a besieger to penetrate into any of the works, without being exposed, on all sides, to the fire of the besieged, who are under cover; and from artillery and musketry it is scarcely possible for an assailant to shelter himself. Coehorn published a work on fortification before he had acquired much practical experience, and therefore did not follow it in fortifying Bergen-op-Zoom, which is allowed on all hands to be his masterpiece.

Since Vauban's time several improvements have been suggested, particularly by Cormontaigne, who entered the corps of French engineers in 1716, nine years after Vauban's death, and died a mareschal-de-camp in 1750. Some account of the system of Cormontaigne will be found in a subsequent part of this article. The three methods delivered by Belidor are all applicable to an octagon of two hundred toises; those of Scheiter, distinguished into great, mean, and little, in imitation of Pagan, require the exterior sides of the polygon to be, respectively, two hundred, a hundred and eighty, and a hundred and sixty toises. Steven, a Fleming who wrote on fortification, exemplified his method of construction on a hexagon. Fritach, a Pole, proposed two methods, which he exemplified on different polygons. Dogen, a Dutchman, published a large volume on fortification, in which, after enumerating various modes employed by different writers for determining the salient angle, he selected three as the most approved, and proposed as many methods of construction, one of which is borrowed from Fritach, the Pole. Pietro Sardi, an Italian, suggested a peculiar method of construction on a hexagon. The Sieur de Fontaine found the flanked or salient angle of the bastion by adding fifteen degrees to half the angle of the figure, from the square up to the dodecagon, in which last it becomes ninety degrees, and at this he continued it in all the higher polygons. He also constructed outwards, and, in every regular figure, made the curtain equal to seventy-two toises, the face of the bastion to forty-eight, and the flank, which he placed perpendicularly to the curtain, to eighteen toises, or a fourth part of the curtain. Ozanam and Muller delivered each four methods of construction, the particulars of which will be found in their respective works. In 1751, Charles Bisset, who as an engineer-extraordinary served with the Duke of Cumberland in the Netherlands, and was present during the siege of Bergen-op-Zoom by the Mareschal Lowendahl, published a treatise on the theory and construction of fortification, in which there are many sensible and judicious remarks; and the same general description may be applied to an *Essai sur la Fortification, ou Examen des Causes de la grand supériorité de l'Attaque sur la Defense*, published anonymously in 1755. In a work entitled *Science de la Guerre*, which appeared at Turin eight years before the date last mentioned, a new method of construction is proposed, in which the principal objects to be attended to are, that there be mines under all the works, and that a regular communication be kept up with the chambers by means of subterraneous galleries, to be resorted to in proportion as the enemy approaches the body of the place. The third volume of the *Œuvres Militaires* contains some useful observations and maxims relative to irregular fortification; and in the Supplement to the *Rêveries* of Mareschal Saxe, by Baron d'Espagnac, the subject of fortification generally is amply discussed, and an accurate description given of the different means of attack and defence.[1]

---

[1] Mallet constructs outwards, making in every figure or polygon the demigorge equal to a fifth part of the side of the interior polygon or figure, the capital of the bastion equal to a third part of the same side, the curtain equal to three fifths or thrice the demigorge, and the angle of the flank equal to 98°. The faces of the bastions and the flanks are determined by the lines of defence, which are razant. From these data all the other lines and angles are easily found.

[2] See his work *De l'Attaque et de la Defense des Places*, passim.

Of the more recent treatises on fortification, by far the most elaborate and complete is that of M. de Bousmard, entitled *Essai Général de Fortification, d'Attaque et de Défense des Places, dans lequel ces deux Sciences sont expliquées et mises l'une par l'autre à la portée de tout le monde;* a work which enjoys a deservedly high reputation on the Continent, though it has hitherto been comparatively but little known in this country. It is remarkable for great accuracy and research, and may be considered as embodying in itself every thing that is valuable in connection with the subject of which it treats. M. de Bousmard's idea is, that officers of the line should be entitled to exercise those functions which have hitherto been universally reserved for officers of engineers; and he even goes so far as to ridicule the idea of the latter forming a separate body in the army. He is of opinion that every officer should, when required, be qualified to act as an engineer; and to furnish the necessary information for this purpose, he has entered into those minute details which are absolutely essential to be known in order to direct the construction of fortresses, and the works necessary for the attack or the defence of strong places, but which are not at all requisite in order to discern the influence of the one or to determine the nature of the other. Proceeding on the same principle, he has further hazarded some questionable opinions, and indulged in abstract and delicate discussions, which are certainly out of place even in such a work, and which appear but little calculated to benefit persons possessing only a superficial acquaintance with the matters forming the subject of these disquisitions. M. de Bousmard's work, therefore, though intended to serve as an elementary treatise on fortification, is much too elaborate and refined ever to be used as such, and also too expensive for the pecuniary means of a great number of inferior officers, whose instruction the author professes to have had chiefly in view. But to teachers of fortification it is altogether indispensable; and as long as the science and practice shall continue on their present footing, it will be deservedly considered as the most comprehensive and valuable work on the attack and defence, as well as the construction, of all kinds of fortification.[2]

With regard to Carnot's *Traité de la Défense des Places Fortes*, it was written to serve a temporary purpose; and the celebrity which it acquired on its first appearance has for some time been rather on the decline. The more prominent innovations recommended in this treatise were, first, an alteration in the trace or outline of the polygon; secondly, the suppression of the exterior revêtement of the covered way, known as the counterscarp; thirdly, the detachment of the scarp-wall from the rampart, and the construction of the latter without revêtement; fourthly, destructive personal conflict with the besiegers by means of frequent sorties; and, lastly, making vertical fire the basis rather than an accessory of the defence. With regard to the first of these proposals, all of which the reader will find very ably discussed in Jones's *Journals of Sieges in Spain and Portugal*,[3] we have only to remark, that by means of an increased expenditure for retrenchments and casemates, as recommended by Carnot, the strength of particular portions of the polygon may be increased; and that, if he has failed in tracing a perfect front, founded on the basis of Montalembert's system of casemated and reverse fire, he has at least rescued a valuable suggestion from unmerited neglect, and rendered an important service to science by directing the attention of military men to the means most likely to create a barrier against the growing powers of the attack.

The *Traité de Fortification Souterraine, suivi de quatre Mémoires sur les Mines*, by M. Mouzé, lieutenant-colonel of engineers in the French service, was published at Paris in 1804, and is justly considered as the most complete work on the subject it treats of which has yet been given to the public. Subterranean fortification is a branch of the art which, until a very recent period, was wholly neglected in this country, and in which our engineers are still far behind their brethren of the continent. We learn from Colonel Jones's work on the Peninsular Sieges, that the Duke of

---

[1] Besides the writers above enumerated, may be mentioned the Chevalier St Julien, an able engineer, who published a method by which, he asserts, works may be constructed at a less expense, yet in such a manner as to render the defence or attack more formidable; Francisco Marchi, of Bologna, who furnished no less than a hundred and sixty different methods of constructing fortifications; Bombelle, who established three kinds of fortification, called the grand royal (*grand royal*), the mean royal (*moyen royal*), and the little royal (*petit royal*); Blondel, who published a system divided into two principal heads, the great and the little, whose exterior sides are respectively two hundred and a hundred and seventy toises; Donato Rosetti, a canon of Livorno, who wrote on the method of constructing works in what he calls *fortification à rebours*, or fortification in reverse, so denominated because the re-entering angle of the counterscarp being opposite to the flanked angle, it will, according to him, be necessary to attack it from the reverse side of other works; and Antonio de Herbart, major of artillery in the Duke of Wurtemburg's service, who published a treatise on fortifications with what he calls *angular polygons*. The treatise entitled *Nouvelle Manière de fortifier les Places, tirée des méthodes du Chevalier de Ville, du Comte de Pagan, et de M. Vauban, avec des Remarques sur l'ordre renforcè, sur les desseins du Capitaine Marchi, et sur ceux de M. Blondel*, which appeared in 1689, is full of strong reasoning, whence the author deduced a new system, but it contains little that is really original, though it gives numerous references to what had previously appeared, and disposes the different parts in a judicious manner. M. de Montalembert's system of casemated and reverse fire has been in part adopted in the splendid fortress of Alessandria in Italy, constructed under the directions of Napoleon.

[3] Vol. ii. p. 131, *et seqq.*

Wellington's army in Spain was unattended by a single regularly-trained sapper or miner until late in the year 1813; and many valuable lives were sacrificed, from the want of these valuable, or rather indispensable auxiliaries.

SYSTEMS OF PERMANENT FORTIFICATION.

1. *Vauban's First System.*

Before commencing to draw a plan of fortification, it is usual to determine upon some polygon on which to describe it. In this figure, accordingly (see Plate CCXLVI. fig. 1), we have taken the angle of an octagon, and called the length of the side 360 yards.[1] In constructing a fortification, a figure is determined on, as near that of a regular polygon as possible, within which the enceinte or chain of main works is to be contained. The enceinte or body of the place consists of as many bastions, connected with curtains, as there are sides to the figure, and each of these is made as near 360 yards as possible, so that every part may be within range of such arms as are to be employed in its defence.

The *principal* or *outline* denotes the contour or line by which the first figure of the work is defined. This line is supposed to pass along the superior part of the cordon, and is that from which all the other parts of the work are set off.

The *exterior side*, or side of the polygon above mentioned as equal to 360 yards, is that upon which the front of the fortification is described, and it extends from the flanked angle of one bastion to the corresponding angle of the next, as AB. These lines are bisected, and a perpendicular, DC, is drawn from the point of bisection towards the place, its length being proportional to the extent of the exterior side and adjacent angle of the polygon; that is, one sixth for the hexagon and all figures of a greater number of sides, one seventh for the pentagon, and one eighth for the square.

The *lines of defence* AEG, BEH, are drawn from the extremities of the exterior sides through these points, and produced to an indefinite length; and upon the lines so drawn are set off two sevenths of the exterior sides, equal to 102$\frac{6}{7}$ yards, which marks out the point for the shoulder of the bastion E and F. The distance between these points is then laid along the continuation of each line of defence, and a line is drawn connecting them for the curtain GH, from the extremities of which lines are drawn to the point marked off for the shoulder of the bastion, and thus form the flanks. And in this manner is drawn a front of fortification, which being repeated round the sides of the polygon, completes the works of the enceinte or body of the place.

Vauban divided his first system into three parts; namely, the little, the mean or intermediate, and the great. The first he used for small forts of four or five sides, citadels, horn-works, and crown-works, making the exterior sides from 120 to 240 yards, the perpendicular in the square equal to one eighth, and in the pentagon one seventh, and the faces of the bastions in each equal to two sevenths of the exterior side. In the mean or intermediate, which is adapted for all sizes of towns, the exterior side varies from 250 to 360 yards, the perpendicular is one sixth, and the faces are two sevenths. In the great the exterior side varies from 360 to 520 yards. This kind was never adopted for *all* the sides of a place, but only when *one* of these happened to be near a river or a marsh; in which case the distances of the bastions should be so regulated that they may not be out of musketry range from one another. When the curtain becomes unavoidably too long, this defect is in part remedied by erecting on it a flat bastion, which is not so high as the rest of the works.

Ground which will admit of being regularly fortified throughout is seldom or never to be met with, but, nevertheless, the rules of regular fortification must be observed as nearly as possible; that is, the flanked angles should not be less than 60°, the lines of defence should not exceed musket range, and the sides should be lengthened or shortened so as to obtain a well-proportioned front upon each. After an irregular place has been reduced to as regular a form as possible, lines are drawn parallel at the distance of about thirty yards from the houses, in order to give sufficient space for the rampart; and these lines form the interior polygon, which may be fortified inwards by setting off the demigorges of the bastions, and raising their flanks at an angle of 100° with the curtain: Or, the exterior side may be formed and fortified inwards by drawing a line parallel to each of the interior sides; and when the angle is that of a polygon of more than five sides, the distance from the exterior to the interior sides should not be less than 100 yards. If a side extend from 360 to 520 yards, the perpendicular should be diminished to about fifty yards, and the faces of the bastions be made from 100 to 120 yards. When a side is very long, it may be divided into several parts of from 340 to 360 yards each, which may be fortified with flat bastions.

The *ditch* or *fosse* is an excavation of from twelve to twenty-four feet in depth, and from thirty to fifty yards in breadth, surrounding the rampart on the exterior side, and the earth dug out of which serves to raise the rampart and parapet. The side of the ditch next the place forms part of the *escarpe*, the side next the country is called the *counterscarp*, and it is made circular opposite the salient angles of the works. In fig. 1 arcs are described with a radius of thirty yards, opposite the salient angles of the bastions, tangents to which are drawn upon the shoulders of the neighbouring bastions, and thus form the ditch. The general dimensions of a ditch should be such that its excavation, or deblai, would produce sufficient earth, or remblai, for the formation of the works. The breadth varies from thirty to fifty yards, in order that, in passing across it to the assault, the enemy may, for a considerable time, be exposed to the fire of the works; and its depth must also be such as to render difficult the escalade of the parapet, as well as to prevent the besiegers at the crest of the glacis from being able to see to breach the lower part of the revêtement of the escarpe. The line of the counterscarp is drawn from the rounding at the salient angles of the bastions upon the shoulders of the bastions next adjoining, in order that the whole of the ditch may be defended by the fire of the flanks of the collateral bastions. Ditches are of three kinds; wet, dry, and such as may occasionally be rendered either wet or dry. The wet ditch is calculated to prevent sudden surprises or assaults, excepting during hard frost, as in the attempt made to surprise Bergen-op-Zoom in the year 1814; but, independently of this exception, the number of bridges of communication, which require continual repair, and the difficulty of making sorties, which a wet ditch creates, render it extremely inconvenient. A dry ditch, which is capable of containing works for its own defence, and by means of which communications round the works may more easily be maintained, is therefore preferable to a wet one; but the third kind, which unites the advantages of the other two, should, when practicable, be preferred to either. It is only in particular situations, however, that the advantage of such a ditch can be obtained.

---

[1] Although it has been common to employ the French toise as the standard measure for drawing plans, yet as the British lineal measure of yards and feet has of late years been adopted by our engineers, we shall conform to the same usage.

The *tenaille* is a work placed in front of the curtain. It is formed by the continuation of the lines of defence, at the distance of ten yards from the angle of the shoulder; the ends are then drawn parallel to the flanks of the bastions; it is made sixteen feet broad; the angle formed by the meeting of the two lines which determine its rear is then cut off, at the distance of ten yards, parallel to the curtain; and another line is drawn, at the distance of sixteen yards, parallel to this, and forming a small curtain upon the line of defence or front of the tenaille. The relief or height of the tenaille is determined by that of the neighbouring flanks, and it has a parapet of seven or seven and a half feet in height, and from twelve to fifteen feet in thickness. The use of the tenaille is to cover the postern gate, which is often made in the curtain or flank; when the ditch is dry, to protect the troops who may be formed behind the work for the defence of the ditch; and when the ditch is a wet one, to cover the boats which may be collected for the same purpose. It also serves to augment the defence, as its fire, from being more horizontal, and nearer than that from the flanks, is of course proportionally more effectual.

The *ravelin* or *demilune* is a work constructed opposite the curtain, and composed of two faces meeting in an outward or salient angle, with two demigorges formed by the counterscarp. Its use is to cover the curtain, the gates, and the flanks of the bastion. The ravelin is constructed as follows: Ten yards are set off along the faces of the bastion; from the shoulder an arc is described from the curtain, upon the perpendicular produced, with a radius of 160 yards; from this intersection lines are drawn bearing upon the points set off at ten yards from the shoulders of the bastion, but not further than the lines of the counterscarp, and at the intersection of the lines of the counterscarp or re-entering angle; and six yards are set off on the capital or line bisecting its angle, whence lines are drawn parallel to the lines of defence till they meet those of the counterscarp. Stairs, called *pas-de-souris*, are constructed here in order to facilitate the entrance of the ravelin from the ditch. The ditch in the ravelin, which is twenty-four yards in breadth, is made circular at the salient angle, and drawn parallel to the faces till it joins the main ditch.

The *covered-way* is a space of ten yards in breadth, extending all round the counterscarp of the ditch, and covered by a parapet of from seven to nine feet in height, with a banquette. The superior part of this parapet forms a gentle slope towards the country, which terminates at the distance of from forty to seventy yards; and this slope is called the *glacis*. The covered-way serves for drawing up troops in order to make sorties, and costs less than any other part of the works in proportion to the difficulty of taking it. In the salient and re-entering angles of the covered-way spaces are contrived which have been denominated *places of arms*.

The *salient places of arms* are formed by the circular parts of the counterscarp, and the prolongation of the branches of the covered-way till they intersect. The *re-entering places of arms* are constructed with two faces, forming a salient angle of 100° with the covered-way. The demigorges of the re-entering places of arms are generally from twenty-four to thirty yards; but when they are intended to contain a redoubt or entrenchment, they are from forty to forty-eight yards. The re-entering places of arms are meant to flank the branches of the covered way, and to contain the troops for its defence. The salient places of arms also serve for assembling the troops destined to defend the covered-way.

Traverses are constructed across the covered-way, upon the prolongation of the sides of the ravelins and bastions, perpendicular to the line of the counterscarp; they are from eighteen to twenty feet thick, and serve to cover the troops from the enfilading fire of the enemy. Other traverses should be constructed between these, so that the distance from the one to the other should not exceed thirty-six or forty yards. Openings are cut into the parapet of the covered-way about ten or twelve feet wide, in order to keep up the communication from one part to another round the ends of the traverses, which, however, may be shut by a gate when required. In the more improved systems of Cormontaigne and others, these passages are constructed in such a manner that each can be defended by the fire from the traverse in rear of it.

The *glacis*, as already stated, forms a gentle slope or declivity from the parapet of the covered-way towards the country, and varies from forty to sixty yards. Its parapet cannot be ruined by the fire of the enemy; it covers the revêtement of the body of the place; and being an inclined plane, it can be easily seen and defended from any part of the works.

The *rampart* is an elevation of earth, being the part of the works situated next to the town. It must be thick enough to receive a mound of earth, called the parapet, and also leave sufficient space behind it for working the guns, as well as room for the defenders to pass round freely. The ditch is immediately in front of the rampart, the faces of which are reveted or built up with stone walls, backed interiorly, at every fifteen or twenty feet, by buttresses or counterforts of masonry, to strengthen it. The rampart is divided into the *interior slope*, the *terre-plein*, the *banquette*, the *parapet*, and the *exterior slope* or *escarpe*. See fig. 4, *profile*.

The *revêtement* or face of masonry around the work on both sides of the ditch is intended to prevent the earth forming the rampart from falling into the ditch. To ascertain the proper thickness of masonry for this purpose has always been a work of considerable trouble and difficulty. Colonel Pasley of the royal engineers has given the following rules: 1*st*, For full scarped revêtements without berms, and for demi-revêtements having berms equal to one fourth the height of the masonry, the thickness of the wall should be seventeen sixtieths, and the length of the counterforts or buttresses one fifth of their height. 2*dly*, For demi-revêtements without berms, the mean thickness of the wall should be three tenths, and the length of the counterfort one fifth of the height. 3*dly*, For counterscarp revêtements, having only to retain simple terre-pleins, the mean thickness should be one fourth, and the counterfort one sixth of the height. In all these cases, Colonel Pasley supposes the revêtement to be countersloped, that is, to have the exterior slope in a vertical plane, and the interior face inclined, so that the base of the wall may be broader than its upper surface by one fifth of its height; and he also supposes the counterforts to be rectangular, and the intervals between their centres to be equal to four times their width. 4*thly*, He recommends that the foundations be made deeper in rear than in front, and that the courses of masonry form an angle with the horizon of about 10°; and, excepting at the exterior points, where it should be made horizontal, to prevent the rain from penetrating, that the interior face of the wall should be of an irregular form. In order to diminish the lateral pressure of the earth against the revêtements, several tiers of arches may be built between the counterforts in the form of segments of a circle.

The *cordon* is a round projection of stone, about a foot in diameter, which goes quite round the revêtement wall near the top, and serves to throw the drip of rain off the face of the masonry. It is also a considerable obstacle to besiegers, in placing their ladders for escalade against the escarpe.

The *profile* or *section* of Vauban's first system is given in Plate CCXLVI. fig. 4, in order to illustrate the relative relief or height of the respective works, and also to show the command which each has over the others. By *command* is meant the vertical height of one work above another, or above the country. When the height of the rampart, including that of its parapet, is twenty feet, and that of the parapet of the covered-way is nine feet above the plane of the site, then the rampart will have a command of twenty feet over the country, and eleven feet over the crest of the covered-way; and the latter, again, will have a command of nine feet over the field. There are three sorts of command, namely, in front, in rear, and in enfilade. That in front is when any eminence directly faces the work which it commands; that in rear is when the eminence is behind the work; and that in enfilade is when the eminence is situated laterally on the prolongation of any line or work. The last, which is the most dangerous kind of command, is best remedied by raising the salient works exposed to it, or by erecting traverses. In drawing this figure, a line, called the line of site, and supposed to be the surface of the ground on which the fortification stands, is drawn, and perpendiculars are erected on it equal to the respective heights of the different parts of the works corresponding to the lines in the figure. Thus *a* shows the terre-plein of the rampart, *b* the banquette or step to enable the soldiers to fire over the parapet, *c* the parapet, *d* the revêtement, *e* the escarpe, *f* the counterscarp, and so on.

2. *Vauban's Second and Third Systems.*

Having thus endeavoured to explain, with as much minuteness as possible, the principles of Vauban's first system, we trust, from what has been said, that no great difficulty will be experienced in understanding the methods of other engineers who have constructed works varying but little in the main from those prescribed by this system, whilst even these varieties have arisen from difference of situation and local peculiarities, more than from any other cause. The same general observation, indeed, applies to the other methods of construction followed by Vauban himself, who, in his second and third systems (see Plate CCXLVI. fig. 2) merely modified, according to circumstances, the principles upon which the first is based. When this celebrated military engineer was called upon to repair or improve the fortresses of Landau, Brisach, and others, and found these places already surrounded with strong walls surmounted by small towers at the angles, he did not, as some might have supposed, proceed to destroy these defences, but, with his accustomed judgment and ability, he immediately took advantage of them, and constructed, nearly in the same proportions as in his first system, large counterguards or bastions in front of the towers which crowned the angles of the wall. And by this method an important object was attained; for, as in front of each tower, or rather tower-bastion, there ran a ditch which cut off all communication between it and the counterguard, so the enemy, even if they should have succeeded in establishing themselves in the counterguard, would still have another ditch to cross, and another wall to breach, before they could attempt to give the assault.

There is so little difference between the second and third systems of Vauban, that a description of the former will be sufficient to enable the reader to distinguish and appreciate the peculiarities of the latter. In the second system, the interior side of the polygon, from the centre of one tower-bastion to that of the next, is supposed to be equal to 240 yards, and from its extremities, at the distance of twenty-four yards, perpendiculars are erected equal to thirty-six yards, for the flanks of the tower-bastions. A line is then drawn parallel to the interior side AB, till it meets the oblique radius of the polygon, or line drawn from the centre of the polygon, bisecting its angle, and this being done on both sides of the angle, forms the tower-bastion. The oblique radius is then produced seventy-eight yards, and lines of defence are drawn to the angle where the tower-bastion joins the curtain or line AB. On these lines of defence, the faces of the counterguard, or exterior bastion, are set off equal to . . . yards, and from the point forming the shoulder, flanks are directed to a point set off on the line AB, at the distance of seventy yards from its extremities. From the salient angles of the tower-bastions arcs are described with a radius of fourteen yards for the breadth of the ditch, and tangents to these arcs are drawn parallel to the faces of the tower-bastion, but stopped where they would meet a line drawn from the salient angle of the tower-bastions, at the distance of twenty yards from the flanks.

The *tenaille* is the same as in the first system, excepting that, at its ends, it is carried down till it meets the line drawn between the flanked or salient angles of the tower-bastions. The *ditch* in front of the counterguards, or, in other words, the main ditch, is constructed in the same manner as in the first system. The *ravelin* is formed by setting off ninety yards from the re-entering angle of the counterscarp, and directing its faces to points set off on the counterguards, at the distance of twenty yards from the shoulders. A flank is formed by cutting off the corners of the ravelin at the distance of fourteen yards on its demigorge, and twenty on its face; and this flank serves for the placing of guns in such a manner that their fire may be directed into the counterguard, or into the ditch before them, as occasion may require. Again, at the distance of forty-eight yards from the re-entering angle of the counterscarp, lines are drawn parallel to the faces of the ravelin for the *redoubt;* a ditch is formed in front of this, and parallel thereto, about eighteen feet in breadth; and the redoubt thus constructed has a command of four feet over the parapet of the rampart, as the tower-bastions have over the counterguards. The *covered-way* and *glacis* are formed as in the first system. It sometimes happens that redoubts are constructed in the re-entering places of arms; in which case their demigorges are made from fifteen to forty yards, and their faces set off at an angle of a hundred degrees, as before.

3. *Cormontaigne's System.*

The difference between the systems of Vauban and Cormontaigne may easily be discovered by an examination of Plate CCXLVI. fig. 3. Vauban makes the faces of his bastions two sevenths of the exterior side, and Cormontaigne one third. Vauban, in his first system, produces the faces of his ravelin to the distance of ten yards upon the face of the bastion from the shoulder, and in his second and third systems, to the distance of twenty yards; but Cormontaigne makes the capital of his ravelins about 120 yards, and produces the faces to the distance of thirty yards from the shoulder; by which means the flanks are better covered, and the bastions and ravelins are enlarged. And this is an advantage; for he is thus enabled to construct a larger redoubt in his ravelin, the curtain and flank are also better covered, and, as the former is shorter, communications are more easily kept up between the bastions. Cormontaigne gives the same breadth to his covered-way as Vauban, but he arranges in a different manner the communication round the extremities of the traverses, as may be seen by inspecting the plate. By this chequer order, or zigzag line of communication, the passage round the extremity of one traverse may be defended by the fire of the other in its rear, or nearer to the body of the place, and the advance of assailants along the covered-way completely checked.

4. *The Modern System.*

The modern system, which is shown in Plate CCXLVII. fig. 2, varies but little from Cormontaigne's. Its perpendicular is one sixth of the exterior side, and the faces of the bastions are one third. The flanks are at right angles with the lines of defence, whereas in Vauban's system they form an angle of about eighty-two degrees; which is not so good, because, in the modern system, the guns placed in the flanks can fire straight along the ditch without being moved or turned on their platforms. The ravelin is formed by setting off thirty-four yards from the shoulder angle of each bastion along the face, which line forms one side of an equilateral triangle, the vertex of which, opposite the centre of the curtain, forms the salient angle of the ravelin. The redoubt of the ravelin is formed by drawing its faces parallel to those of the ravelin from the shoulder angle of the parapet of the bastion; and it has flanks with a ditch about twenty yards in breadth. The *cavalier* in the bastion is drawn parallel to the faces of the bastion, at the distance of forty-eight yards. The ditch on the faces is ten yards in width, but there is no ditch on the flanks. The *coupure*, or cavalier retrenchment, is drawn perpendicular to the faces of the bastions, at thirty-four yards for the counterscarps of the coupures, whilst the scarps are at ten yards, and parallel to these.

5. *Coehorn's System.*

This system, which is shown in Plate CCXLVII. fig. 1, is particularly adapted for the low and swampy country of Holland, where alone it has been practised. It is not, therefore, deemed necessary here to enter into any details respecting it. The great width of the ditch, which is nearly twice as broad as in Vauban's systems, and the narrow space between the flanks, constitute the principal differences between the methods of these celebrated engineers; a difference, as already observed in speaking of Coehorn, caused by the different descriptions of ground on which their respective works were erected.

6. *Outworks.*

Plate CCXLVII. fig. 3, shows several kinds of outworks, as a horn-work *g*, tenaillons *k* and *k*, bonnet *d*, lunettes *a* and *d*, an entrenched bastion *e*, batardeau *f*, and caponnière *h*. These, and other works of a similar description, are constructed for the purpose of occupying some of the ground which might otherwise be of service to the besiegers; but their application must of course depend upon certain localities, and the judgment of the engineer must therefore determine, in each particular place, which is best adapted to the ground, and most proper to be employed with reference to the general defence of the place.

ARMAMENT OF FORTRESSES.

Having thus endeavoured to describe as briefly as possible the principal systems of fortification, it only now remains for us, before quitting this branch of the subject, to say a few words respecting the means of defending a place after it has been fortified. And here we may observe, that it is difficult to lay down any exact rules as to the proportion of ordnance, ammunition, and stores of every kind required for the defence of a fortified place, seeing this must necessarily vary according to the particular situation of each fortress, the system on which its works have been constructed, and the species of attack to which it may be exposed. If, for example, one of the sides be covered by a morass, swamp, or any other obstruction which it is difficult or perhaps impossible to surmount, it must be obvious that, in this case, a smaller proportion of artillery will be required than if the fortress were equally accessible on every side; and, on the other hand, a maritime fortress, accessible at all points, will necessarily require for its defence a larger proportion of ordnance than if it were only assailable on one or a few of these points. Where every front is equally exposed to attack, all must of necessity be equally prepared.

On this subject, however, there have been established certain maxims, of which the following appear to be the most important: First, the proportion of ordnance, ammunition, and stores, should never exceed the quantity necessary for a brave and resolute defence. Secondly, those points which are considered as being most exposed to attack should be most completely armed, whilst the partial armament of the remaining points may suffice. Thirdly, for each of the faces of the bastions which are liable to be attacked, five or six pieces of ordnance should be allotted; for each of the flanks of these bastions, four; for the faces of the ravelins, from five to seven; for the lunettes, when there are such, four pieces of ordnance should be reckoned; besides two or three pieces for each of the places of arms in the covered-way. Supposing, therefore, that one front of a place is to be completely armed, the proportions of ordnance required will be, for the faces of the bastions from ten to twelve pieces, for the two interior flanks from six to eight, for the faces of the ravelins from five to seven, and for five places of arms from ten to fifteen; making the total of ordnance for one front from thirty-one to forty-two pieces. Fourthly, when a place is exposed to attack on two consecutive fronts, the armament of each should be augmented one half; when it is threatened with attack on detached fronts, the armament should, in that case, be doubled. Fifthly, each of the other fronts should merely be provided with such a proportion as to secure it against insult. Lastly, from the foregoing maxims, it appears that a hexagon, having only one front exposed to attack, requires from fifty-eight to sixty-eight pieces of ordnance on such front, whilst in more extensive places, six, eight, or ten pieces should be added for each additional front.

The next consideration is the proportion which the several kinds of ordnance should bear to one another. And here let it be remembered that ordnance of the higher calibres is not the only description which ought to be employed. In many cases medium, and even light guns are more efficacious; for when only troops or working parties are to be fired at, light guns will answer every purpose, as the range of the shot is nearly equal to that of larger guns, and they are of course much more manageable, and may be worked with greater rapidity. But short guns of heavy calibre are best adapted for the flanks; and, generally, the large or heavy ordnance should only be employed to destroy the besiegers' batteries and dismount their guns. The flank guns being only required for the defence of the ditch, short pieces of large calibre, as carronades, which throw a heavy charge of grape or canister shot, are the most proper to be employed. The light guns, as they can easily be withdrawn, should be placed on the covered-way and places of arms, and on outworks of every description. The heavy long guns and mortars, as they are not so easily moved, should be within the body of the place, and as they require a great quantity of ammunition, they should be less frequently used, and only upon urgent occasions. A judicious economy of ammunition is a duty incumbent upon every governor or commandant of a fortified place attacked. The conduct of General Chassé in the defence of the citadel of Antwerp was a model in this respect. From the commencement till the close of the attack, scarcely a single shot was needlessly expended by the garrison.

ATTACK AND DEFENCE OF FORTIFIED PLACES.

Having thus treated of that important branch of fortification which is denominated permanent, and which, being applied solely to the defence of towns, is not liable to be destroyed except by an enemy, we now proceed to consider the attack of fortified places, the general system of which was introduced by Vauban, and so far perfected by that great engineer that it has ever since served as a model for the plans of his successors.

"La résolution des sièges," says the Mareschal, "est une affaire de cabinet. Elle est une suite naturelle de la supériorité que l'on croit avoir sur ses ennemis; mais leur exécution étant une des plus sérieuses, des plus importantes, et des plus difficiles parties, elle demande aussi le plus de mésure et de circonspection." He then goes on to state that the success of sieges depends on several circumstances, such as, "1. Du secret, sans lequel il est difficile de réussir: 2. Des forces que l'on a sur pied pour attaquer les places des ennemis et defendre les siennes: 3. De la disposition des ennemis; car s'ils sont réunis, et aussi forts que nous, ils peuvent nous empêcher d'en faire: 4. De l'état des magazins les plus à portée des lieux sur lesquels on peut entreprendre: 5. De la conjoncture des tems, parce que tous ne sont pas propres aux siéges, et rien n'étant plus ruineux que ceux d'hyver, on les doit eviter tant qu'on peut: 6. Des fonds nécessaires à leurs dépenses; car l'argent est le nerf de la guerre, sans lui on ne sçauroit réussir en rien. Ce sont là des mésures à prendre de longue main, qui doivent être dirigées à loisir; et aprés tout cela, quand on croit les avoir bien prises, souvent tout échappe; car l'ennemi, qui n'est jamais d'accord avec vous, pourra vous interrompre.... Il faut bien peser toutes ces considérations, avant que de se déterminer; et prendre toujours si bien son tems, que l'ennemi ne puisse vous tomber sur les bras avant vos établissemens."[1]

A siege, therefore, being one of the most arduous undertakings in which an army or corps d'armée can be employed; one in which the greatest fatigue, hardships, and personal risk are encountered, and in which the prize can only be won by complete victory; it is obvious that, upon the success or failure of such an enterprise may depend the fate of a campaign, sometimes that of an army, and perhaps even the existence of a state. Of this the failures before Pavia in 1525, before Metz in 1552, before Prague in 1557, before St Jean d'Acre in 1799, and before Burgos in 1812, present instructive examples. By the first, France lost her monarch, the flower of her nobility, and all her Italian conquests; by the second, she was saved from destruction, whilst thirty thousand of her enemies perished; by the third, the greatest warrior of his age, Frederick the Great, was brought to the very brink of destruction; by the fourth, the most successful general of France, and perhaps the greatest commander that any age or country has produced, was stopped short in his career of victory; and by the last, a beaten enemy gained time to recruit his forces, concentrate his scattered corps, and regain that ascendency of which the victory at Salamanca had for a time deprived him. Innumerable other instances of the disastrous consequences usually attendant on the failure of sieges might easily be produced; but those which have just been referred to are sufficient to establish the importance of the undertaking, and to show that the dearest interests of a country may frequently be staked on the sure and speedy reduction of a fortress.

It is therefore of the greatest importance to a state that the sieges undertaken by its armies should be carried on in the best and most efficient manner possible, or, in other words, that by a due combination of science, labour, and force, these operations should be rendered not only short, but certain, and unproductive of any great expenditure of life. But the sieges undertaken by the British have almost never united these three indispensable conditions; and with regard to those which took place during the contest in the Peninsula, it is well known that various defects of organization, and particularly the want of a body of men, such as sappers and miners, trained to the labour required at sieges, not to mention the inexperience of the engineers, and an inadequate supply of matériel, necessitated a departure from all established principles and rules of attack, and consequently led to a waste of life wholly unprecedented in modern sieges. Till late in 1813 the army was unattended by a single sapper or miner: regular approaches were therefore impracticable: it was necessary, in almost every case, to take the bull, as the saying is, by the horns; the last operation of a siege scientifically conducted, namely, battering in breach, was the first, or almost the first, undertaken: and the troops were marched to the assault whilst the defences remained nearly entire, and exposed to every species of destruction which the unreduced means of the besieged could bring to bear against them. The army of a country which has outstripped all others in the useful arts and in mechanical improvements, was left wholly unprovided with those appliances which at once economise labour and life, and serve to render both most effectual for the purposes to which they are applied. But, notwithstanding this great anomaly, which is chargeable against the government alone, and not against either the nation or the army which in the most adverse circumstances so nobly sustained its reputation, it may be observed that, in all periods and in all countries, the means employed for the reduction of fortresses have generally increased and become more overwhelming and irresistible in proportion to the advancement of knowledge and the improvement of the useful arts; and that in Europe during the last two centuries, the extensive diffusion of wealth and knowledge, accompanied by an unprecedented development of talent, all more or less directed towards military movements, has caused the results of sieges, and indeed of almost all the operations of war, to depend much less on individual exertion or casual displays of heroism, than on mere combination and expenditure. This may be made apparent by a slight retrospect of the sieges of the sixteenth century.

At the period here referred to, the art of disposing the several works of a fortress so as to cover each other, and to be covered by their glacis from the view of an enemy, was either unknown or disregarded; whilst the small quantity of artillery in use, its unwieldiness, and the great expense and difficulty of bringing it up, occasioned so little to be used in sieges, that the chief object in fortifying towns was to render them secure against escalade and surprise, by means of lofty walls or altitude of situation. All places fortified prior to the sixteenth century are invariably of this construction. And as the simplicity of the fortresses to be attacked necessarily gave the same character to the operations directed against them, so, in those days, every thing was effected by daring courage, without the aid of science; and gallantly contending in individual combat, or fearlessly confronting danger, were considered as the highest qualities of a besieger. Thus the contest dragged on for months, in petty but sanguinary affairs, and the most persevering or the most hardy troops, however ill organized or supplied, were the most dreaded, and not unfrequently the most successful. But when artillery became more moveable, and large quantities began to be employed in sieges, lofty and exposed walls no longer opposed any adequate barrier; large breaches were speedily effected; places which had formerly resisted for months were carried in a few days; and hence, in order to restore an equality of defence, it became necessary to screen the ramparts from distant fire. The attempt to gain security by concealment rapidly advanced towards perfection, whilst the means of the besiegers remained the same; and between the middle of the sixteenth and commencement of the seventeenth century, works were so skilfully disposed and so well covered, that the defence of towns obtained a temporary superiority over the attack as the latter was then practised. Of this the obstinate and successful defences made by the Dutch against the Spaniards during the reigns of Philip II. and Philip III. may be cited as remarkable examples.[1]

---

[1] *De l'Attaque et de la Défense des Places*, pp. 1 and 2. Hague, 1737, 4to.

But unhappily for this pre-eminence, Vauban appeared on the scene, and, supported by Louis XIV., who brought to the attack of fortresses a vast and costly preparation in ordnance, ammunition, and materials, perfected in the early offensive campaigns of that monarch a covered mode of attack, which, by a singular combination of science and labour, and by the steady advances of a few brave men well trained to such work, rendered comparatively easy the reduction of places capable of for ever defying the rude violence of multitudes. These increased means of attack, to which it was found impossible to oppose a successful resistance, caused the art of concealment or covering to be further studied, till at length, in well-constructed fortresses, not a single wall remained exposed to view, and the sap and the mine became as necessary as the gun and the mortar to the success of a besieger. To render this intelligible to the general reader, it may be proper to introduce here a descriptive sketch of the progress of a modern attack, from the excellent work of Sir John Jones, already referred to.

" The first operation of a besieger," says that able and experienced engineer, " is to establish a force able to cope with the garrison of the town to be attacked, at the distance of six or seven hundred yards from its ramparts. This is effected by approaching the place secretly in the night with a body of men, part carrying entrenching tools, and the remainder armed. The former dig a trench in the ground parallel to the fortifications to be attacked, and with the earth that comes out of the trench raise a bank on the side next to the enemy, whilst those with arms remain formed in a recumbent posture, in readiness to protect those at work, should the garrison sally out. During the night this trench and bank are made of sufficient depth and extent to cover from the missiles of the place the number of men requisite to cope with the garrison, and the besiegers remain in the trench during the following day, in despite of the fire or sorties of the besieged. This trench is afterwards progressively widened and deepened, and the bank of earth raised till it forms a covered road, called a parallel, embracing all the fortifications to be attacked; and along this road, guns, waggons, and men securely and conveniently move, equally sheltered from the view and the missiles of the garrison. Batteries of guns and mortars are then constructed on the side of the road next the garrison, to oppose the guns of the town, and in a short time, by superiority of fire, principally arising from situation, silence all those which bear on the works of the attack. After this ascendency is attained, the same species of covered road is, by certain rules of art, carried forward, till it circumvents or passes over all the exterior defences of the place, and touches the main rampart wall at a spot where it has been previously beaten down by the fire of the batteries erected expressly for the purpose in the more advanced parts of the road.

" The besiegers' troops being thus enabled to march in perfect security to the opening or breach in the walls of a town, assault it in strong columns; and being much more numerous than the garrison defending the breach, soon overcome them, and the more easily as they are assisted by a fire of artillery and musketry directed on the garrison from portions of the road only a few yards from the breach; and which fire can, at that distance, be maintained on the defenders of the breach until the very instant of personal contention, without injury to the assailants. The first breach being carried, should the garrison have any inner works, the covered road is by similar rules of art pushed forward through the opening, and advanced batteries are erected in it to overpower the remaining guns of the place; which effected, the road is again pushed forward, and the troops march in security to the assault of breaches made in a similar manner in those interior works, and invariably carry them with little loss." But as it is always an object to preserve the life of even a single soldier, so, when time is abundant, the loss of men attendant on the assault of breaches under these favourable circumstances may be avoided, by pushing up the covered road through the breach, without giving the assault, and thus, by art and labour, the strongest defences frequently fall without any exertion of open force."

From this description it must be obvious that the most important object at a siege is to carry forward the covered road to the walls of the place; that all the other operations are secondary to and in furtherance of such an advance; and that hence the efficiency of armies at sieges depends upon their ability to complete the road at a small expense of life. But in forming this covered road, different degrees of difficulty are experienced in proportion as it advances. At its commencement, the work, owing to the distance from the fortifications, which is usually about six hundred yards, and not being straitened for space, can easily be performed by the common soldiers. But when the road or trench has arrived within a fair range of musketry, or three hundred yards from the place, then particular precautions are required; yet the work at this stage is not so difficult as to prevent its being executed by soldiers who have had a little previous training. At the last stage, when the approaches have been pushed close to the place; when to be seen is to be killed; when mine after mine blows up the head of the road, with every officer and man on the spot; when the space becomes so confined that little or no front of defence can be obtained; and when the enemy's grenadiers sally forth every moment to attack the workmen, and deal out destruction to all less courageous or weaker than themselves; then the work becomes truly hazardous, and can only be performed by selected brave men, called sappers, who have acquired the difficult and dangerous art from which they derive their name. An indispensable auxiliary to the sapper, however, is the miner, who, in the exercise of his art, requires even a greater degree of skill, conduct, and courage than his principal. The duty of a miner at a siege is to accompany the sapper, to listen for and discover the enemy's miner at work, and to prevent his blowing up the head of the road, either by sinking down and meeting him, in which case a subterranean conflict ensues, or by running a gallery close to that of his opponent, and forcing him to desist from working by means of suffocating compositions, and various arts of chicanery, the knowledge of which he has acquired from experience. Without the aid of skilful miners, sappers would be unable to execute that part of the covered road forming the descent into the ditch, not to mention other portions in the formation of which the assistance of the miner is equally indispensable; and without their joint labours and steady cooperation, no besiegers' approaches ever reached the walls of a fortress.

---

[1] *Journals of Sieges in Spain*, by Colonel Sir John T. Jones; *Preliminary Observations on the Attack of Fortresses.*

But a siege, though it calls for great personal bravery, unremitting exertion, and extraordinary labour in all employed, yet, if scientifically prosecuted, is alike certain in its progress and its result. More or less skill and exertion in the contending parties may in some degree prolong or abridge its duration; but the sapper and the miner, when skilfully directed and adequately supported, will ultimately surmount every obstacle. On the other hand, sieges undertaken by armies destitute of these auxiliaries, as was that of the Duke of Wellington in Spain, are hazardous in the extreme. Their only chance of success consists in scrutinizing the exterior of a fortress, in order to discover some spot whence, from the irregularity of the ground, or fault of construction, the main escarpe wall may be seen at a distance sufficiently great to enable the ordinary working parties to approach with the covered road, and there to establish batteries for breaching the wall or forming an opening through it into the place. When this is effected, the troops at once advance to the assault of the breach, as in the sixteenth century, thus losing the shelter of the covered road at the moment when the fire of the place becomes most powerful and destructive; and as the fire of the besiegers' distant batteries is necessarily suspended during the assault, in order to avoid killing their own storming party, the garrison can therefore with impunity mount their ramparts and employ every kind of weapon, missile, and instrument in their defence. All the chances are thus in favour of the besieged; for should the columns of attack, under all these disadvantages, arrive in good order at the brink of the ditch, they must descend into it by a wall from fourteen to sixteen feet in depth, which cannot fail to break their order and throw them into confusion; and as no new formation can be attempted in a spot where death is incessantly showering down on them, the assailants rush to the breach more like a rabble than a solid column. From this moment success hinges on the individual and confident bravery of the officers and troops, and the unshrinking firmness of the general commanding, in at once encouraging and supporting their efforts. But although these qualities, when united in a high degree, may, at a great sacrifice of life, enable the assailants to overcome all resistance, yet an assault of this nature, attempted under ordinary circumstances and feelings, has almost invariably proved unsuccessful. Indeed it may be laid down as the general result of experience, that should an army unprovided with sappers and miners, and the necessary materials and means to render their services efficient, be opposed to a place fortified according to the modern system, with its walls completely covered, all the usual methods to reduce it would prove unavailing; no period of time nor sacrifice of men would be sufficient to purchase success, and the prudent course would be to decline an attempt pregnant with hazard, perhaps ruin.[1]

Having thus given a general description of the methods of attack, we shall now subjoin, on high authority, a view of what is considered as necessary for the proper defence of fortified places. An order issued by the French minister of war in 1813 contains directions on the subject which are almost universally applicable, and therefore deserve a place here. Every commander is directed to consider his garrison as liable to be unexpectedly attacked, and to pass at once from a state of peace into one of war or siege, either by rebellion, by unlawful assemblies, by the presence of an enemy, by surprise, or by sudden assault; in a word, by unforeseen causes, of which the history of war offers numerous examples. He is therefore ordered, even in time of peace, to fix his plan and arrangement for defence, according to such supposed attacks as may appear most probable, and to determine, for the principal cases which may be likely to occur, the necessary posts, reserves, and movements of the troops, and to take measures to ensure the due and active cooperation of every corps of the garrison. He ought, particularly, to make himself thoroughly acquainted with, *first*, the ground beyond the place which may be within the circle of action, of investment, and of attack; *secondly*, the fortifications of the place, its interior, its buildings, its military edifices or establishments; *thirdly*, the garrison, the means of the place in artillery, in ammunition, and in other stores of every kind; *fourthly*, the population to be subsisted in time of siege, the men capable of bearing arms, the master and journeymen artificers fit to be employed either on the works or in case of fire; and, *fifthly*, the provisions, materials, tools, and other resources which the town itself and surrounding country can furnish, and which it might be necessary to secure in case of siege. In order to enable governors and commanders to comply with these instructions, which are equally clear and precise, the minister proceeds to detail their principal duties, according to the circumstances in which they may find themselves placed; but for these we must refer to the general order itself, which is a masterpiece of its kind, and in all probability emanated directly from Napoleon himself. Its object appears to have been to produce a belief, that by taking proper precautions, and making a full use of means previously provided, the defence might be rendered equal, if not superior, to the attack; and although it is acknowledged on all hands that the idea of attaining such an advantage for the defence is, generally speaking, fallacious, yet the importance of the directions embodied in the order is not on that account diminished, and where they are duly observed, the nature and extent of the resistance must be materially increased.

---

[1] *Journals of the Sieges in Spain*, Preliminary Observations.—"These considerations," says Sir John Jones, to whom we are indebted for the above account of the various modes of attacking fortified places, "have for many years had their due weight with the great powers of Europe, and induced them to form and keep up, as integral portions of their military strength, every necessary auxiliary for the reduction of fortresses; and their sieges have in consequence become certain and comparatively bloodless. But England, constitutionally jealous of permanent military establishments, always discountenanced military organization and military preparation till the hour of need; and with respect to sieges, they being of rare occurrence, and moreover exclusively offensive operations, even carried her jealous feelings beyond the bounds of rational prudence; for, possessing a corps of officers professionally educated and well grounded in the science of attack and defence, she denied them every requisite establishment to render their acquirements availing, and most unreasonably expected her armies to reduce the skilfully fortified and well-covered places of the nineteenth century with means inferior to those brought against the exposed and ill-constructed places of the sixteenth and seventeenth centuries." And what was the immediate consequence of this irrational jealousy and niggardly parsimony? Contrary to all ordinary calculation, the fortresses garrisoned by the French in Spain were reduced; but at what a prodigious expenditure of life was this effected? In the several attacks upon Badajoz, two of which, from extrinsic circumstances, proved abortive, a little army was sacrificed; as many men, in short, as would have been sufficient for the consumption of *ten* sieges undertaken with adequate means, and conducted according to the ordinary rules of science. But this is not to be understood as involving any reflection against the military talents of the general or the professional ability of the engineers. General Foy, in his work on the war in the Peninsula, has indeed made such a charge, condemning the mode of attacking fortresses adopted by the British in Spain as unskilful and inefficacious, and bringing it forward as indisputable proof of the low state of military knowledge in our army. But it should be recollected that the adoption of this mode was not a matter of choice, but of necessity; and that if it was in its own nature rash, hazardous, and inefficient, the fact of its having been directed against Ciudad Rodrigo and Badajoz with such rapidity of development and certainty of result as to outstrip the calculations of the French marshals, deceive the vigilance of French governors, paralyse the science of the French engineers, and baffle every defensive effort of the French garrisons, is surely no evidence of deficiency in military talent and professional skill. The objections to this mode of attack are insurmountable and decisive; that it succeeded in the instances referred to is merely a proof what British soldiers, even when acting under the greatest disadvantages, are capable of accomplishing.

Attack of the Citadel of Antwerp.

For the elucidation of the principles above stated, we now proceed to give a sketch of the attack on the citadel of Antwerp; first, because this was the most regular and scientific siege which had taken place for many years; and, secondly, because, as a practical operation, an account of it must not only be more interesting, but at the same time more instructive, than any description whatsoever of the formal theoretical plans which are usually drawn in the military schools.

The French army employed to cover and conduct the attack of the citadel of Antwerp, in November and December 1832, was placed under the command of Marshal Gerard, and amounted to 54,000 infantry, 6000 cavalry, and 6450 engineers, artillery, and pontonniers, making a total of 66,450 men, and 14,300 horses, with 144 pieces of siege and 78 of field artillery. On the 24th of November Marshal Gerard established his head-quarters at the village of Berchem, about 2500 yards from the citadel, and issued orders to commence operations in the evening as soon as it became dark. The garrison of the citadel, under General Baron Chassé, amounted to 4470 men, with 144 pieces of ordnance of all calibres, and abundance of ammunition and stores.

At eight o'clock P. M. on the 29th November the French troops destined for this service consisted of 18 battalions, 900 artillery, and 400 sappers, in all about 17,140 men, assembled at the depôts of intrenching tools. The flank companies of these brigades, supported by twelve eight-pounders and a strong piquet of cavalry, formed the covering party under the direction of General Haxo, by whom and the officers of his department (the engineers) the first parallel and approaches were traced out, whilst General Niègre and the officers of artillery marked the sites of the projected batteries. The first parallel leaned on the covered-way of the right face of Montebello, and extended towards Kiel, its nearest point being about 325, and its farthest 435 yards from the advanced front of the citadel. The distance covered by the first parallel, from right to left, was 1870 yards, and that by the approaches 3750 yards. The communications from the right and centre debouched from the Malines Chaussée, in the village of Berchem, parallel to the road leading from that village to the Harmony and St Laurent; that from the left commenced near to the garden called Heinrich's; whilst a fourth, on the extreme right, sprung from the covered-way of the left flank of Montebello, opposite to the first traverse.

On the second night, from 30th November to 1st December, five approaches were pushed on in front of the first parallel; two in the direction of the capital of the Toledo bastion, two upon that of the Lunette St Laurent, and one, being the fifth, terminating in a place of arms on the extreme left. From the 1st to the 2d December two zigzags were added to the approaches; one from the centre, in the direction of the gorge of St Laurent, and the other on the right, diverging towards the curtain, between the Toledo and Fernando bastions. The badness of the weather sadly incommoded the workmen, and prevented the artillery getting the guns into battery. Between the 2d and 3d December four zigzags were made in front of the approaches on the right and centre, and half a parallel was formed to complete the place of arms constructed on the left during the night of the 30th November. The heads of the zigzags were pushed to within 135 yards of the glacis. The batteries Nos. 1, 2, 3, 4, 5, 6, and 9, with two for mortars in the rear, were armed, and ready to be unmasked at a moment's notice. The arming of Nos. 7, 8, and 10, on the extreme left, was impeded by the difficulties of the ground. From the 3d to the 4th December, the second parallel was traced and commenced, its right leaning on the foot of the glacis of the counterguard, its centre and right 130 yards distant from the place of arms in the covered-way of the Toledo bastion, and its left towards the right of the covered-way of St Laurent, at 90 yards from the crest, and 15 from the foot of its glacis. The length of the second parallel was 1250 yards, and, together with its approaches from the first parallel, it occupied 3025 yards of ground. By the greatest exertions batteries Nos. 7, 8, and 10 were armed during the night. This completed the armament, and, at 11 A. M. on the 4th, the embrazures were unmasked, and the signal being given, the batteries opened their fire from centre to flanks, and maintained it steadily during the day.

From the 4th to the 5th of December an approach was pushed on from the second parallel, almost in a direct line upon the salient angle of St Laurent, and an entry was made into the covered-way by a return to the left. The garrison discovered this, and opened a sharp fire from the Lunette; a lodgment was, however, effected near the spot usually occupied by the first traverse. At this time the garrison suffered much from the fire of the besiegers. From the 5th to the 6th the lodgment made the previous night in the covered-way of the salient place of arms of St Laurent was prolonged as far as the first traverse. But the besieged kept up so vigorous a fire that the French engineers were obliged to renounce the flying and adopt the full sap. The zigzag in the counterguard, being about three feet in width and four in depth, was conducted along the parapet, nearly to the extremity of the right flank, and within 180 yards of the counterscarp of bastions Toledo and Fernando; and two lodgments, blinded with fascines, were made in the parapet for six rampart guns to enfilade the covered-way of the Toledo bastion. In the mean time a steady fire was kept against Kiel, the ravelin in its rear, and the Paciotto bastion. From the 6th to the 7th a battery of 24-pounders near the village of Burcht on the left and Hoboken on the right opened on the gunboats which flanked the French post at the Melk Huys. It was intended to assault St Laurent this evening; but as the lunette was found to be too well protected by *trous-de-loup*, the project of storm was abandoned, and the regular method of descent, passage, and mine, determined on.

Between the 7th and 8th of December a shell penetrated the blindage of the laboratory, and setting fire to loaded bombs and other combustibles, caused considerable havoc. A battery for six mortars, E, on the right between Nos. 3 and 4, now opened its fire; another, F, also for six mortars, was traced behind the centre of the parallel; and platforms for four mortars were laid down near Montebello. The fire of these batteries was directed on the Toledo bastion and the buildings within it. On the previous day jets of smoke and flame were seen to issue from the Great Barracks, and, in spite of every exertion on the part of the garrison, the whole building soon became involved in a general conflagration, which raged with such fury that by the evening of the 8th it was entirely consumed.

From the 9th to the 10th of December the operations against St Laurent were renewed with great activity, and the sap advanced to the crotchet of the second traverse, whilst that intended to debouch upon it from its right was likewise pushed on. The principal operation of the night, however, was the opening of the third parallel, 130 yards in advance of the second, its right debouching beyond the Boom Chaussée, from the branch running into the covered-way of the counterguard, and its left uniting with the boyau parallel to the foot of the glacis of St Laurent. At this time the garrison suffered much from the vertical fire of the mortars and howitzers, especially the great mortar, and the new-model eight-inch howitzers. Until the year 1822, the eight-inch howitzer in common use in France measured three feet six inches French, and weighed 1096 lbs., or twenty-three times the weight of the loaded projectile, whilst its calibre was equal to a solid shot of 80 lbs., and contained 65 ounces of powder. The new-model howitzer is an improvement on the Russian licorne and the Spanish heavy howitzer, perfected by Colonel Paixhans. The raft for the blinded descent into the ditch was brought up to the lodgment, and a second descent *à ciel couvert* was commenced to the left of the first. The third parallel was, at the same time, improved and widened. A little after dusk on the 10th the besieged made a sortie, which was driven in, but not until damage enough had been done to occupy the French all the night of the 10th and morning of the 11th in repairing it. From the 11th to the 12th three rafts were got ready, and placed in the descents to the ditch; they were about twelve feet by eight. At dusk the miners returned to the escarpe, and, in an excavation made the previous night, fixed two petards, which, by their explosion, produced a fissure in the wall; and a serjeant having immediately entered the hole, commenced a gallery under the centre of one of the arches. At 11 A. M. on the 12th the battery mortars, H, on the extreme right of the second parallel, opened their fire, which, combined with that from the others, told severely on the Toledo bastion. The miners still continued their work under the Lunette St Laurent, and commenced chambers for three mines. The fourth parallel was widened during the day.

Between the 12th and 13th of December the miners were at work in the chambers under St Laurent, which were not yet completed. On the right the covered way of the left face of the Toledo bastion was crowned to within sixty-five yards. From the 13th to the 14th, after nearly sixteen nights of open trenches, the arrangements for the assault of St Laurent were completed, and orders were issued to prepare for the storm. Much, a great deal too much, was said of this out-work, defended by little more than a hundred men, one five-and-a-half inch howitzer, two coehorn mortars, and a six-pounder. The mine being reported charged, the blinded descent into the ditch was pierced as soon as it became dark, and every thing got ready for the assault. Three storming parties, consisting of the flank companies of the 65th regiment of the line, were posted in readiness, with a column of reserve; and at 5 A. M. on the 14th, every preparation being completed, the match was applied to the saucissons of the mines. After a few moments of suspense, three successive explosions took place, and the escarpe immediately presented a wide and practicable breach. The fascines for crossing the ditch had been injured by the explosions; but after a little delay the storming party entered almost without opposition, and made prisoners one lieutenant and forty-eight rank and file, the others having escaped into the citadel. Thus fell the Lunette St Laurent.

After this, operations were carried on against the citadel, and at 11 A. M. of the 21st December the battering in breach commenced, and continued for two days. At length, on the 23d, when a practicable breach had been formed, and Marshal Gerard was about to deliver the assault, the garrison surrendered, after as gallant a defence as any recorded in military history, though more remarkable for its passive than its active character. When Marshal Gerard, accompanied by the French princes, entered the fortress, they found General Chassé in a casemate in the Alba bastion, which he had occupied during the siege. On their progress from the gate to the governor's quarters, they passed through a scene of desolation and ruin, intermixed with painful and disgusting objects, which baffles all description. The whole, indeed, presented an unparalleled chaos of black and smouldering destruction; and, with the exception of the principal powder magazine, two or three service magazines, and the hospital, not a building was standing. The terrepleins of the bastions were ploughed into deep ruts by the shells; the gorges were encumbered with heaps of fallen rubbish; and though the casemates and subterranean communications were not perforated, all of them had sustained damage from the incessant explosion of shells, and they emitted an offensive, nay, almost insupportable odour, caused by the number of men who had been crowded into these vaults. Every thing was of course said by the victors to console and flatter the vanquished. When Count Gerard took his leave of General Chassé, he observed to the brave veteran, "that it was high time to surrender; that he had gallantly and honourably done his duty, and that he ought not to have held out a day longer." With a fortress reduced to a heap of ruins, a garrison exhausted and extenuated, and a breach sufficiently wide to admit a column formed upon a front of a hundred, it would not have been bravery, but madness, to attempt, under such circumstances, to stand an assault.

This operation, so instructive in a military point of view, is also remarkable as having occurred in a time of general peace. It would be out of place here to enter into any detail of the complicated series of events and negotiations out of which so singular an occurrence arose: we shall therefore content ourselves with observing, generally, that Great Britain and France, as joint guarantees for the integrity and independence of Belgium, having failed in every attempt to procure the evacuation of Antwerp by means of negotiation, were obliged, by the faith of treaties, to have recourse to force. Hence the siege, politically considered, is to be viewed merely as an ejectment executed against the king of Holland, who had refused to renounce possession, unless compelled to do so.[1]

---

[1] The account of the siege given above is abridged from that published in the *United Service Journal*, and which is decidedly the best that has yet appeared

The following is a list of the different batteries, with the direction of their fire respectively:—

	Number of Batteries.	Twenty-four Pounders.	Sixteen Pounders.	Eight-inch Howitzers.	Ten-inch Mortars.	Distance in Yards.	Direction of Fire.
	1	6	...	2	...	535 and 550	Battering the left face of Toledo, and gorge of St Laurent.
Opened on the 4th and 5th December.	2	...	2	2	...	500	Ricochetting the left face of Toledo.
	3	4	...	2	...	640	Battering the left face of the Ravelin.
	4	...	3	2	...	650	Ricochetting left face of the Ravelin.
	5	6	2	1	...	680 and 430	Battering right face of Toledo, and ricochetting left of Toledo.
	6	...	2	2	...	700	Ricochetting left face of Toledo.
	7	6	2	1	...	380 and 700	Ricochetting left face of St Laurent, and battering right face of Paciotto
	8	...	3	2	...	465	Ricochetting left face of Ravelin.
	9	...	...	6	...	820	Battering salient angle of Paciotto.
	10	8	...	...	...	650 and 520	Battering left face of Ravelin, and Lunette of Kiel.
	A	...	...	...	10	850	Not armed.
	B	...	...	...	9	1000	Body of the Citadel.
	C	...	...	..	11	1050	....
	D	...	...	...	10	850	....
	...	30	14	20	40	......	....
	11	4	...	...	...	500	Battering the right face of Toledo.
Between the 8th and 18th.	12	...	3	...	...	435	Battering the Batardeau.
	13	...	4	...	...	220 and 275	Battering the left face of Ravelin.
	E	...	...	...	6	500	The body of the Citadel.
	F	...	...	...	6	490	....
	G	...	...	...	6	650	....
	H	...	...	...	6	380	....
	K	...	...	...	8	600	....
	14	6	...	...	...	50	Breaching Battery.
	15	6	...	...	...	350	Counter-battery against the left flank of Fernando.
	16	...	...	...	...	125	Six pierriers on the Ravelin and Toledo.
	L	...	...	...	10	250	Terreplein and rampart of Toledo.

The French brought against this place 66,450 men, 14,300 horses, and 222 guns of all descriptions; and they lost during the siege 108 killed, and 695 wounded, total put *hors de combat* 803. The Dutch had 4937 men in the garrison, of whom they lost 122 killed, 369 wounded, and 70 missing, total 561.

Siege of Dantzick.

Having thus given an example of an interior and passive defence, we shall now, in further illustration of the principles already laid down, advert to one of a different if not opposite kind. The siege of Dantzick, whether considered with reference to the magnitude of the operation, the difficulties to be surmounted by the besiegers, or the active and varied character of the defence, was certainly one of the most memorable events in the campaign of 1807. Before the war of 1806 and 1807, the fortifications had been much neglected, because, from the position of the place, no one suspected that it would have to sustain a siege. But when the battles of Iena and Auerstadt had entailed destruction on the Prussian army, and laid open the kingdom, General Manstein, who commanded at Dantzick in the absence of Field-marshal Kalkreuth, the titular governor, had laboured with much activity in improving the exterior works, and particularly in causing them to be strongly palisaded. It is necessary, therefore, to describe the principal defences at the period when the place was invested by Marshal Lefebvre, at the head of the tenth corps of the Grand Army, and immediately before the commencement of the trenches on the 1st of April 1807.

The city of Dantzick, traversed by the Moltau, was surrounded with large ditches filled by that river, the waters of which, retained by several sluices, formed, to the eastward, a vast inundation, which, reaching on one side to the suburbs of Ohra and St Halbrecht, and on the other to the dikes of the Vistula, extended about four leagues, and covered two thirds of the eastern fronts. On the north, the Vistula runs about two hundred and sixty yards from the covered-way, leaving a space between the left bank and the glacis of the place, consisting of an impracticable marsh, intersected by some canals; and at its embouchure, distant nearly three miles, the banks were defended on the right by the fort of Weichselmunde, and on the left by an intrenched camp in the small island of Neufahrwasser, intended to cover and protect the arrival of such succours as might come from the seaward. The ground adjoining the banks of the Vistula being intersected by canals and covered with marshes, was extremely unfavourable to a besieger, as it rendered it difficult for him to form establishments or raise works of proper solidity, and forced him to extend his quarters, disseminate his troops, and multiply his posts. At the period in question, this inconvenience was the more severely felt, because the besieging force was inferior in numbers to that of the garrison, and it required the most vigilant caution to occupy numerous posts without unduly weakening it. The communication between the place and the fort of Weichselmunde was maintained by a series of redoubts constructed on the borders of the Vistula, and particularly by the advantageous position of the isle of Holm, which enabled the besieged so to approximate the fire of the place to that of the fort as only to leave between them an interval of about fourteen hundred yards, and also to communicate with Weichselmunde by the canal of Laack, in spite of batteries which the besiegers might establish at Schellmühl. The French, therefore, could not attempt to throw a bridge over this part of the Vistula until they had made themselves masters of the isle of Holm. On the west, two chains of hills, separated by the valley of Schidlitz, covered this part of the enceinte; and the prolongations of these hills were crowned by two forts, that of Bischopsberg and that of Hagelsberg, which, being connected by continuous intrenchments, formed a second enceinte, flanked upon one side by the inundation of the Moltau, and upon the other by the left bank of the Vistula. This new enceinte, though constructed of earth, and without revêtement, was nevertheless secure against insult; and as the covered-way, as well as the foot of the scarps and counterscarps, bristled with strong fraises, which served instead of revêtements, the besiegers had no hope of succeeding by a coup-de-main, and were therefore obliged to proceed by a regular attack.

From this description of the defences of Dantzick, it is easy to perceive that the difficulties attending the operation must have been very great. The principal of these, as stated by General Kirgener,[1] who, until the arrival of General Chasseloup, directed the attack, were, 1*st*, that Marshal Lefebvre had at first an army inferior to that of Marshal Kalkreuth, and that this army was in a great measure composed of new troops, all those destined for the siege not having then arrived; 2*dly*, that, owing to the badness of the roads and the inclemency of the season, the artillery experienced the greatest difficulty in bringing up its convoys, whilst the establishment of the batteries was retarded, and a scarcity of ammunition sometimes prevailed; 3*dly*, that the place requiring an immense circumvallation, which, in fact, could not be completed until after the arrival of reinforcements, the corps of troops which occupied the quarters were extremely weak, and hence could neither furnish a sufficient number of workmen at a time, nor even the number of men necessary for guarding the trenches; and, 4*thly*, that the besiegers had no good plan of the place, no idea of the depth of the ditches, and that, as the accidents of ground in front of the fortifications were extremely diversified, they could only be reconnoitred in proportion as the works advanced. These circumstances, the necessity of concentrating the greater part of the troops close to the camp of Neufahrwasser, by which succours arriving by sea might debouch, and, lastly, the advantage which the besieged had been able to preserve of remaining masters of part of the suburbs, determined the chief engineer, after the investment had been effected, to direct the principal attack against the Hagelsberg, and a false one against the Bischopsberg fort. The true point of attack was the long branch of lines in the plain connected with the bastion on the right of the Hagelsberg; "c'était là le défaut de la cuirasse;" but, for the reasons above stated, General Kirgener was induced to direct his approaches against the fort itself.

As the details of this great siege would fill a considerable volume, all that our limits permit us to attempt is merely to indicate the principal occurrences. On the 1st of February 1807 the troops of General Dombrowski began to approach Dantzick, and took up a position at Mewe, upon the left bank of the Vistula. On the 15th General Ménard, commanding the Baden contingent, arrived at the same point, and repulsed a detachment of the garrison of Dantzick, which had advanced from Dirschau to attack him. On the 23d General Dombrowski, having been reinforced, received orders to attack a large detachment of the enemy which occupied an advantageous position at Dirschau and its environs. The combat here was obstinate and sanguinary; but the Prussians, though intrenched in a church and a churchyard, were dislodged and driven back, chiefly by the Poles, who, exasperated by their long resistance, put to death without mercy all who fell into their hands. After the combat of Dirschau, General Manstein no longer sought to obstruct the distant approaches. The troops destined to form the besieging army now arrived in succession, and the parc of artillery began to be formed. On the 12th of March Marshal Lefebvre found himself in a condition to close in on the place; and the troops of the garrison having withdrawn, he distributed his own in the following positions: A battalion of French light infantry at Ohra, a Saxon battalion at St Halbrecht in the Burgerfeld, and two others at Tiefensee and Kemlade; the Poles occupied Schonfeld, Kowald, and Zunkendin; some battalions took post at Wonnenberg, Neukau, Schudelkau, and Sniekau; the Saxon cuirassiers and light horse were stationed at St Halbrecht and Guirsehkens; the 19th regiment of French chasseurs at Burgfeld, and the 23d at Schudelkau; the Baden dragoons and hussars at Wonnenberg, and the Polish lancers at Langenfurt. On the 16th the marshal attacked the village of Stolzenberg, which he carried after a warm resistance, as he did also the suburb of Schidlitz to which the Prussians had retired; and on the 18th the place was entirely invested, with the exception of the eastern part, which, by the isle of Nehrung, communicated with Königsberg. Field-marshal Kalkreuth now arrived in Dantzick, and assumed the command of the place. The next operation of the besiegers was the attack of the isle of Nehrung, which, after a severe and protracted struggle, was carried in the most gallant manner, and measures immediately taken to secure possession of this important conquest. A bridge was also established on the Vistula, and various works constructed to check the attempts of the enemy either on the side of Dantzick or on that of Pillau. At this time the governor, who, besides the burgher militia, had under his command a garrison of 18,000 men, made a sortie for the purpose of destroying the works already commenced by the besiegers; but the attempt failed, and the Prussian columns were compelled to retreat into the place without having obtained the smallest success upon any point.

As it had been decided that the principal attack should be directed against the fort of Hagelsberg, favoured by two false attacks, the one directed against the intrenched camp at Neufahrwasser, and the other against Bischopsberg, and also by two other secondary attacks on the left bank of the river, ground was broken on the night of the 1st and 2d April, at the distance of sixteen hundred yards from the palisades. The approaches were pushed forward with the greatest vigour, and on the night of the 11th the second parallel was commenced by means of the flying sap. On the morning of the 12th the marshal ordered the batteries to be armed, which was accordingly done.

---

[1] This officer, the head of the engineer staff, and one of the most distinguished in that branch of the service, fell in the field of battle at Bautzen, where he received his death-wound from the same ball which killed Duroc, the grand marshal of the palace, and the intimate friend of Napoleon.

On the 13th the enemy made a sortie in force, attacked the Saxons with great impetuosity, carried a redoubt constructed upon the mamelon of Hagelsberg, and even penetrated to the head of the trenches; but they were ultimately repulsed, though not without difficulty and loss. By the 23d all the batteries of the first and second parallels, and those of Stolzenberg, were armed, and emplacements were provided for field howitzers, in order to throw shells into all quarters of the city. At daybreak on the 24th the batteries were unmasked, and though the garrison returned the fire with the greatest vivacity, that of the besiegers soon obtained the ascendency, committing great ravages in the place. Being apprised of this circumstance, Marshal Lefebvre summoned the governor, who replied in a manner worthy of himself. The fire of the mortar and reverse batteries continued during the 25th, in the course of which a new battery was constructed between the low flanks of the Stolzenberg; and the direction of some others changed, in order to batter the right bastion of Bischopsberg, the fire of which had greatly incommoded the French batteries. During the day of the 26th, the fire on both sides was exceedingly animated; but at seven in the evening, that of the garrison suddenly ceased, and a column of six hundred Prussian grenadiers, followed by two hundred workmen, soon afterwards sallied out of the place. As the sortie had been foreseen, however, preparations were made to repulse it, which was done by a combined attack in front and on both flanks, in consequence of which the whole column was either killed or taken. Meanwhile the works were vigorously pushed forward at all points. The batteries of Stolzenberg were united with the attack on the Bischopsberg; emplacements were prepared for batteries *à ricochet;* at the attack of the Lower Vistula the works were continued, and a tongue of land situated at the extremity of the isle of Holm taken possession of and isolated by means of a cut; whilst at the principal attack the greatest exertions were made to prolong the right of the third parallel, and enlarge the communications. On the 30th April the batteries of the besiegers, augmented by several pieces which had arrived from Warsaw, thundered on the place, in different quarters of which conflagrations now appeared; and the besieged replied by the fire of all the batteries of the front of the attack, directing more than thirty pieces on a redoubt, which fired with the greatest effect. But as the fire of the besiegers had made little impression on the exterior fortifications, which were of earth, it was during the first days of May directed chiefly against the palisades, in order to facilitate the assault of the place; and the utmost activity was at the same time evinced in extending, improving, and urging forward the attack; whilst, on the other hand, the garrison showed equal vigour in obstructing the approaches and destroying the works of the besiegers. In fact, notwithstanding the address of the French artillery, that of the garrison still remained effective, because it had not been possible to ricochet the lines of the fortifications, and the resources of the besieged in munitions of all kinds were more considerable than those of the besiegers.

On the urgent recommendation of General Chasseloup, who had by this time assumed the direction of the attack, it was now decided that the isle of Holm should be assaulted, as the possession of it would enable the besiegers to construct new batteries, to take in reverse the front of the attack. The besieged had spared no pains for the preservation of this important post. In the night of the 6th and 7th of May, however, it was attacked, and, after a desperate resistance, carried; whilst the possession of it was secured by works added to the intrenchments which had just been stormed, and the batteries were turned against the place. At the principal attack the fire of the besiegers had also mastered that of the besieged; and Marshal Lefebvre was preparing to assault the fort of Hagelsberg, when a Russian corps d'armée under the command of General Kamenskoi arrived by sea, and disembarked at the intrenched camp of Neufahrwasser.

At the moment of landing his troops, General Kamenskoi was ignorant of the capture of the isle of Holm, and he was disconcerted to find such an obstacle to his communications with the place. This occasioned delay, which proved fatal to his enterprise; for had he attacked immediately on landing, it is not improbable that he would have succeeded. It was only on the 15th of May, however, being the fourth day after the disembarkation, that he resolved to make an attempt to succour the besieged city. He began to debouch at four in the morning, and, under cover of a brisk cannonade, formed his force, consisting of from eleven to twelve thousand men, in four columns of attack. The onset was impetuous, and at first the Russians gained ground, thrice attempting to penetrate the French line; but they were ultimately repulsed at all points, and forced to retreat with great loss to the intrenched camp. Field-marshal Kalkreuth made no attempt to second this attack by means of a general sortie, which would have placed the French between two fires; and by its failure the fate of Dantzick was decided. Such was the issue of the only effort made by the allies to relieve this important fortress.

The works of the besiegers were now pushed forward with redoubled vigour; and in the course of the following day preparations were made for the assault of Hagelsberg. Foreseeing this, Marshal Kalkreuth resolved to make a last effort to destroy the nearest works of the besiegers, and for this purpose ordered a grand sortie, which took place on the evening of the 20th May; but although the Prussians fought with all the fury of despair, they were at length driven back, and pursued even into the ditch of the place. On the 21st the army of siege was reinforced by the arrival of the troops of Marshal Mortier, part of which had remained before Colberg; the marshal himself quickly followed; and orders were immediately issued for the assault of Hagelsberg. Before giving the signal, however, Marshal Lefebvre again summoned the governor of Dantzick, who, having no longer any hope of being succoured, and convinced that the besiegers were in a condition to make themselves masters of the fort of Hagelsberg, showed a disposition to capitulate. A suspension of arms was accordingly agreed to, and this was followed, on the 24th of May, by a capitulation, the principal conditions of which were similar to those which the field-marshal himself had granted to the garrison of Mayence in 1793.[1]

FIELD FORTIFICATION.

Field fortification is the art of constructing all kinds of temporary works in the field. An army intrenched, or fortified, in the field, produces, in many respects, the same effect as a fortress; for it covers a country, supplies the want of numbers, stops the advance of a superior enemy, or, if he chooses to risk a battle, obliges him to engage at a disadvantage. "In a war of march and manœuvre," says Napoleon, "if you would avoid a battle with a superior army, it is necessary to intrench every night, and to occupy a good defensive position. Those natural positions which are ordinarily met with are not sufficient to protect an army against superior numbers without recourse to art. Those who proscribe lines of circumvallation, and all the assistance which the science of the engineer can afford, deprive themselves gratuitously of an auxiliary which is never injurious, almost always useful, and often indispensable. It must be admitted at the same time that the principles of field fortification require improvement. This important branch of the art of war has made no progress since the times of the ancients. It is even inferior to what it was two thousand years ago. Engineer officers should be encouraged in bringing this art to perfection, and in placing it on a level with the rest."[1]

---

[1] Dumas, *Précis des Evenemens Militaires*, tom. xviii. chap. 19, p. 123. *Relation authentique du Siege de Dantzick.* "Les principales conditions de la capitulation furent que la garnison sortirait avec armes et bagages, drapeaux déployés, tambour battant, mèche allumée, avec deux pièces d'artillerie legère et leur caissons attelés de six chevaux, pour être conduite aux avant-postes de l'armée Prussienne à Pillau, en passant par l'île de Nehrung, et en cinq jours de marche. Cette garnison s'engageait à ne pas servir contre l'armée Française pendant un an." (Dumas, *ubi supra.*)

Whenever Napoleon had time and occasion for strengthening his position by field-works, he acted upon the principles recommended in the above extract, as almost all his predecessors had done. In the wars which followed the revolution of 1688, in those of Queen Anne's reign, and during the Seven Years' War, we find the commanders of each period, William III. the Duke of Marlborough, Marshal Villars, Marshal Saxe, Frederick II. and Marshal Daun, practically exemplifying their conviction of the great utility of field-works. A few redoubts saved Peter the Great at Pultowa, and enabled him to gain a decisive victory over his formidable antagonist; and at Borodino, some slight open field-works, thrown up by the Russians, caused the French great loss, and rendered too costly to be of almost any avail the victory which, by incredible efforts of gallantry, they gained. It has been argued by some, against intrenchments and field-works, that they have oftener been carried than successfully defended, and that hence incommensurate importance has been attached to them. But it should be remembered, on the other hand, that victory in such circumstances has generally been purchased at an expense which rendered it in effect equivalent to defeat; and that a practice which the greatest commanders of ancient and modern times have approved and followed, cannot be one of doubtful utility. At Austerlitz, where the contending armies were nearly equal, Napoleon was preparing to superintend the construction of intrenchments when he found himself called upon to receive battle; and in Portugal, the Duke of Wellington showed to what importance the art of the engineer might be turned for influencing, not merely the fortune of a campaign, but the fate of a cause. The lines of Torres Vedras, which formed the *ne plus ultra* of the powerful French army under Massena, and from which the tide of war was rolled back broken into Spain, were perhaps the most remarkable works of the kind ever constructed.

"Lisbon," says Sir John Jones, "being situated at the extremity of a peninsula formed by the sea and the Tagus, it is plain that if an army be so posted as to extend across the peninsula, no enemy can penetrate into the city without a direct attack on the army so formed. It was on this principle that the lines covering Lisbon were planned by Lord Wellington. Nature drew the rude outline of a strong defensive position, and art rendered it perfect. A tract of country thirty miles, extending from the mouth of the Zizandra on the ocean, to Alhandra on the Tagus, was modelled into a field of battle; mountains were scarped perpendicularly, rivers dammed, and inundations formed; all roads favourable to the enemy were destroyed, and others made to facilitate the communications of the defenders; formidable works were erected to strengthen and support the weak parts, whilst numerous cannon places, on inaccessible points, commanded the different approaches to them, and gave an equality of defence to the whole position."[2] These lines were not continuous and connected works; they consisted of independent forts, redoubts, flêches, redans, batteries, &c. so placed as to command and enfilade every approach, and to support each other by a cross or a flanking fire. The first line occupied a front of twenty-nine miles between the sea and the Tagus; and by means of telegraphs intelligence could be conveyed from one extremity to the other in a few minutes; whilst the troops were disposed in masses in the rear of the works, ready to move upon any point that might be attacked, by interior communications shorter than any by which the enemy could advance. "The aim and scope of these works," says Colonel Napier, "was to bar the passes, and to strengthen the fighting positions between them, without impeding the movements of the army. These objects were attained; and it is certain that the loss of the first line would not have been injurious, save in reputation, because the retreat was secure upon the second and stronger line, and the guns of the first were all of inferior calibre, mounted on common truck carriages, and consequently immovable and useless to the enemy."[3] Both lines occupied a front of fifty miles, on which there were erected one hundred and fifty forts, mounting in all about six hundred pieces of artillery.

Before this formidable position, defended by a double line of works, and by an army massed and ready to move upon any point by interior communications, the French remained five months, wasting their numbers and resources; until at length, finding it utterly impracticable to force any part of even the exterior line, they were obliged to retire from Portugal, closely followed and harrassed by the army which they had previously driven out of Spain. Yet though the lines of Torres Vedras were thus perfect in themselves, and though one of the ablest of the French generals and a veteran French army were foiled before them, it is not meant to refer to this system of separate field-works as a model to be followed on all occasions; for whilst the old method of covering a considerable front by a continued line of regular bastions and curtains has been universally condemned by modern engineers, it is nevertheless certain that there are situations where a partial application of continued lines may be most judiciously made. In fact, it is not by any fixed rule, but from the nature of the ground and of the position to be defended, that the species of works calculated to be most useful should, in every case, be determined.

---

[1] *Military Maxims* of Napoleon.

[2] *War in Spain*, p. 124. The French army which invaded Portugal under Massena consisted of three corps, under Marshals Ney and Junot and General Regnier, amounting in all to 66,000 infantry and 6000 cavalry, besides a strong body of the imperial guard, which crossed the Pyrenees after the invading force had commenced its march from the neighbourhood of Salamanca. The force collected to oppose this threatened invasion did not exceed 48,000 infantry and 3000 cavalry, of which about a half was composed of Portuguese levies, yet untried in any general action, and of which a very unfavourable opinion still continued to be entertained. In point of numbers, and still more in the composition of their army, therefore, the French had a decided superiority; but all their advantages were neutralised by the defensive position of Torres Vedras.

[3] *History of the War in the Peninsula*, vol. iii.

It must be obvious indeed that even a limited knowledge of the art of war opens a wide field for the exercise of the talents and resources of engineers in field fortification; but the possession of a military coup-d'œil, or of that intuitive judgment which comprehends at a glance the true bearing or character of objects as well as events, is necessary to enable them to convert theoretical stores of information to the best practical uses. In passing through a country, it requires an experienced eye to seize quickly on whatever it presents calculated to prove advantageous or disadvantageous to an army destined to attack or defend it; to appreciate the value of villages, stone-enclosures, and broken ground; to know where to dam up rivers, to scarp heights, to form abattis, trous-de-loup, and other obstacles; to select the best situations for field-forts and redoubts, and the best emplacements for batteries; and to arrange all the defensive means employed, with reference to the number of troops destined to act upon the different parts of the line, so that the movements of the defenders may not be obstructed or retarded, and the communications throughout may be short and easy. The variety of ground, however, upon which military operations are for the most part carried on, precludes the possibility of laying down fixed rules in regard to this subject; the accidents of ground, and the peculiar circumstances of each individual case, must, as already observed, determine the extent and description of the works to be constructed, as well as the obstacles most proper to be formed for retarding, if not obstructing, the advance of an enemy.[1]

At the same time, though the observance of fixed rules be impracticable, general principles are of universal application; and hence some of the received maxims in permanent fortification hold equally good in regard to the construction of field-works. These are, *first*, that the works to be flanked must never be beyond the range of the missiles discharged from the works flanking them, or in other words, never out of the effective range of musketry, that is, from 150 to 200 yards; *secondly*, that the angles of defence should be about right angles; *thirdly*, that the salient angles of all works should be as obtuse as possible; *fourthly*, that though ditches cannot always be as fully flanked as in permanent fortification, yet partial flanking must be carried as far as possible; and, *fifthly*, that in the construction of field-works, reference should not only be had to the direct and immediate obstacles which the work itself is calculated to present to the enemy, and the positive effect of the fire on the approaches to it, but the relative value of the work should likewise be considered, with respect to the support it can receive from or give to other works. These principles or maxims are of invariable application.

It is usual to divide field-works into three classes: *First*, works open at the gorge; *secondly*, works enclosed all round; and, *thirdly*, lines at intervals.

Redans, or simple heads	fig. 1,	are the names given to the various tracings of the first class, or open works.
Double redans, or queues d'hironde	fig. 2,	
Tenailled heads	fig. 3,	
Bastioned heads	fig. 4,	
Redoubts	fig. 5,	are the names given to works of the second class, that is, closed works.
Star-forts	fig. 6,	
Bastioned forts	fig. 7,	
Lines à crémaillières	fig. 8,	are the names given to works of the third class, or lines at intervals.
Lines of redans	fig. 9,	
Lines of tenailles	fig. 10,	
Lines of bastions	fig. 11,	
Lines at intervals	fig. 12,	

The first class are of the simplest kind of field-works, and serve as a mere cover in front of avenues, bridges, causeways, and the like; but being quite open at the gorge, they are only suited for defence when their extremities rest on rivers, or obstacles which prevent their being turned, or when within the full sweeping fire of works in their rear. To increase the strength of a *redan*, its faces are sometimes broken into a kind of flank, as in fig. 1, Plate CCXLIX. The *double redan*, or *queue d'hironde*, fig. 2, is considerably stronger, as the re-entering faces defend each other; the *tenailled heads* in situations which require a greater extent of front; and the *bastioned heads* are also employed in similar circumstances. See fig. 3 and 4.

Redoubts are works closed on all sides; they are constructed of a square or polygonal figure, but most commonly square, as, when of this form, each front can furnish a strong perpendicular fire. Provision should be made for defending the ground before the angles, which, however, are sometimes rounded or cut *en crémaillière*, so that a fire may be delivered from them. See fig. 5.

Star-forts were proposed in order to remedy the defects of redoubts having the ground before them undefended by a flanking fire, so that a cross fire might be delivered from the adjacent sides. But, according to Jomini, "star-forts are the very worst description of fortification; they cannot have flanks, and the re-entering angles take so much from the interior space that it is impossible to place troops and artillery in them sufficient for their defence:" an opinion confirmed by the practice of Sir Richard Fletcher and Sir John Jones in the construction of the lines of Torres Vedras, where the trace of the redoubts was made subservient to the conformation of the ground, to the object in view, and to the protecting them as much as possible from the fire of the enemy's position.

In *bastioned forts*, fig. 7, the principles of construction correspond with those detailed in permanent fortification; and the flanking defence thus obtained for the ditch is nearly perfect. As bastioned forts are only constructed in cases of great importance, no labour or expense should be spared in the formation of such works.

Forts with demi-bastions, fig. 12, are objectionable, as the ditches are only defended by an oblique fire from the sides. The parapets of these works should be of sufficient thickness to resist the fire of the heaviest guns that can be brought against them. In some cases, however, the parapets need only be strong enough to resist the fire of light field-guns, whilst in others it will be sufficient if they serve as a cover to the men within them against musketry. The latter kind is generally that which is thrown up in an evening after taking up a position, and which, if the army does not move next day, it may be considered as necessary to strengthen in some parts, according to circumstances.

---

[1] Shaw's *Course of Field Fortification*, p. 9, et seqq. To the author of this useful tract we have been indebted for valuable assistance in the compilation of the present article, the plates connected with which are engraved from drawings either executed by him or under his inspection.

Continued lines, or connected works, are resorted to in order to enclose the front, or to connect important works or forts. The most simple tracing is that of redans joined together by curtains, fig. 9; but as the ditches of these curtains can only be defended by an oblique fire from the faces of the redans, this defect may be remedied by breaking the curtains so as to form nearly right angles with the faces of the redans, in which case they are called *lines of tenailles*.

Lines en crémaillère have long faces, with flanks perpendicular to these, in order to defend their ditches. When these faces can be directed towards ground upon which it is impracticable to establish enfilading batteries, the construction is considered as good.

Bastioned lines are the strongest trace which can be given to continued lines, when the ground will admit of such. A perfectly regular trace is only suited for level ground. The ditches in field-works are often sloped *en rampe* towards the adjoining flanks, in order that the *deblai*, or quantity of earth excavated, may not exceed the *remblai*, or quantity contained in the mass of the rampart or parapet, a circumstance which often occurs in field-works, where there is seldom any rampart, and only cover sufficient for the defenders.

Lines with intervals, fig. 14, shows the general trace of lines of this kind. The salient works should never be beyond the range of musketry from the re-entering works, and the angles of defence between the two lines should be as near as possible to right angles.

Têtes-de-pont, or *bridge-heads*, are works generally open at the gorge, and whose flanks rest upon a river, in order to cover one or more bridges. The best situation for these works is the re-entering sinuosity of a river. As têtes-de-pont, fig. 13, are usually constructed for the purpose of enabling a retiring army to cross a river in order, and to check an enemy pressing upon it, the tracing and profile should be such as to secure a double advantage to the greatest extent possible. In Sir Howard Douglas's able work on the Construction of Military Bridges will be found much valuable scientific information upon this important subject.

To field-works there are usually added a variety of obstacles, in order to render the approaches more difficult to the enemy; such as *palisades*, *barriers*, *abbatis*, *trous-de-loup*, *chevaux-de-frise*, *harrows*, and *crows'-feet*.

Palisades are strong stakes fixed in the ground, and well sharpened at the upper extremities. They are sometimes placed horizontally in the face of the parapet, in which case they are called *fraises*. *Barrier-gates*, for closing the entrances of field-works, should be made strong enough to resist a sudden attack; they are always placed on the most inaccessible side. *Abattis* are lines of felled trees of considerable size, strongly bound together and picketed down, with the smaller branches cut off, and the remainder sharpened and pointed towards the enemy. They are interlaced as much as possible. Abattis, well disposed, present a formidable obstacle. *Trous-de-loup* are rows of pits, made before a work, in the form of inverted cones, having each a strong palisade or stake in the middle. *Chevaux-de-frise* are formed by inserting iron-pointed stakes, five or six feet in length, into a heavy beam of wood, which will thus, if it be square, present four projecting spears, and if hexagonal, six. Chevaux-de-frise are generally chained together in a line, in order to cover the ground required; and sometimes they are so constructed as to revolve on an axis. *Harrows*, such as those ordinarily used in husbandry, are recommended to be spread, with the teeth uppermost, over the ground by which an enemy, particularly cavalry, is likely to advance to the attack. *Crows'-feet* are pieces of iron, with four points, each four or five inches long, projecting in different directions, and also intended to impede the advance of cavalry.

For *the defence of open towns and villages*, the following methods, recommended by the French minister of war in 1814, are considered as the best that have yet been suggested: "To admit of a town being advantageously intrenched, it is necessary that it should not be commanded within any short distance, that the houses should not be of a construction easily set on fire, and that its extent should not be out of proportion to the means and time at the disposal of the defenders. The first thing to be done is to clear the approaches to the town, by levelling houses, hedges, shrubberies, and whatever may favour the assailants. Wood ought to be cut two feet from the ground, that it may serve to impede the advance of the enemy without masking the fire of the defenders. The next object is to form or complete the enclosure round the town. For this purpose advantage is taken of buildings, walls, and fences applicable to the defence. The openings which remain must be closed by palisades, stockades, or ditches strengthened by abattis. All streets leading out of town must be barricaded. The barricades must be sufficient to resist field artillery, and high enough not to be easily got over; and they ought to be flanked by loopholing the neighbouring houses. When pressed for time, carts filled with dung and the wheels taken off, sand-bags, bales of wool or cotton, and furniture taken from the neighbouring houses, all form good barricades. If there should be any old castle, church, or large substantial building, it should be converted into a keep, by blocking up useless entrances, loopholing walls, and surrounding them by a ditch or abattis. If a town is situated near a stream or river, by which part of it may be covered by inundations, this should never be neglected."

Villages are intrenched on similar principles, and being generally surrounded by gardens with live hedges, the latter may be made use of in forming the lines of defence. If there should only be sufficient troops to defend part of a village or town, a part only should be intrenched and separated from the rest by means of carts and barricades. If there are very few houses, it may be necessary to confine the defence to the church or churchyard, which may in all cases serve as a sort of keep.

The destruction of bridges. Nothing is of greater consequence to a retiring army than to be able to destroy the bridges in its rear, in order to retard the advance of the enemy. Its safety, nay even its existence, may depend upon the success with which this operation is performed. In order to destroy a stone-bridge, a trench in the form of a cross is made in the crown of the arch, the branches of which are about ten feet in length, and sunk to the top of the arch-stones. A hundred and sixty pounds of powder are placed in each cut or trench for an arch three feet thick, strong planks are then laid over the powder, and the whole being well covered with rubbish, the fire is communicated by means of saucisson or long powder-hose. Stone bridges are also destroyed by simply cutting a trench about eighteen inches deep across the crown of the arch, and placing in it 345 pounds of powder covered in the manner just described. This quantity has been found sufficient to destroy semicircular arches of twenty-five feet in span, and three feet in thickness at the key. Wooden bridges may be destroyed in different ways;

they may be pulled to pieces, burned, or blown up. When there is time to take them to pieces, they are unspiked, and the timbers so separated that they may be speedily removed. The best method of burning such bridges is to tar them, and to cover and surround them with fascines or tarred brushwood. When it is necessary to blow up wooden bridges, this may be effected by means of 220 pounds of powder suspended under the superstructure, and fired in the manner above described.

A *ford* is rendered impassable by throwing in large stones, by sinking boards with spikes standing upright in them, by scattering in it crows'-feet, or by placing harrows taken from the neighbouring farms. A low wall may also be built across, so as not to be perceptible above the water; strong stakes may be driven into the bottom, and trees fastened to them; waggons loaded with stones, and the wheels taken off, may in like manner be employed; not to mention a number of other things which may be easily found, and which will answer the purpose equally well. The rendering a ford impassable by such means is only second in importance to the destruction of a bridge, when the enemy whose progress it is desired to retard has either no pontoon-train at all, or has outstripped it by the rapidity of his advance. In this way much valuable time may be gained on the one hand and lost on the other.

(A.)

FORTIFIED ISLAND, an island in the Indian Seas, lying off the coast of Canara, about a mile from the land, a little way north from the entrance into Lake Onore. The island abounds in cocoa-nut, palms, and plantain trees, and has plenty of fresh water. It produces the best sort of cari, which is used by the natives in painting their houses. Its name is derived from its fortifications, which were greatly strengthened by Tippoo Saib, from whom it was taken in 1792, by three British frigates. It is upwards of a mile in circuit. Long. 74. 27. E. Lat. 14. 16. N.

FORTISSIMO, in *Music*, sometimes denoted by FFF, or *fff*, signifies to sing or play very loud or strong.

FORTITUDE, a virtue or quality of the mind, which is generally considered to be the same as courage, though in a more accurate sense the one may be distinguished from the other. Courage may be a virtue or a vice, according to circumstances; fortitude is always a virtue. We speak of desperate courage, but not of desperate fortitude. A contempt or neglect of danger, without regard to consequences, may be called *courage;* and this some brutes possess as well as man. In them it is chiefly the effect of natural instinct; in man it depends partly on habit and partly on strength of nerve. But fortitude being the virtue of a rational and considerate mind, is founded on a sense of honour and a regard to duty.

This virtue takes different names, according as it acts in opposition to different sorts of evil; but some of these are applied with considerable latitude. With respect to danger in general, fortitude may be termed *intrepidity;* with respect to the dangers of war, *valour;* with respect to pain of body or distress of mind, *patience;* with respect to labour, *activity;* with respect to injury, *forbearance;* with respect to our condition in general, *magnanimity.*

The motives to fortitude are many and powerful. This virtue tends greatly to the happiness of the individual, by giving composure and presence of mind, and keeping the other passions in due subordination. To public good it is essential; for without it the independence and liberty of nations would be impossible. It gives to a character that elevation which poets, orators, and historians, have in all ages rejoiced to celebrate. Nothing so effectually inspires it as rational piety; the fear of God is the best security against every other fear. A true estimate of human life, particularly its shortness and uncertainty, together with the numberless evils and temptations to which, by a long continuance in this world, we must unavoidably be exposed, ought by no means to discourage or to throw any gloom on our future prospects, but should teach us that many things are more formidable than death, and that nothing is lost, but much gained, when, by the appointment of Providence, a well spent life is brought to a conclusion.

FORTUNA, the goddess of fortune, worshipped by the Greeks and Romans, became particularly celebrated after the triumphs of the latter. According to Hesiod, she was the daughter of Oceanus and Tethys, the sister of the Parcæ, and the protectress of cities. The sculptor Bupalus represented her with a celestial globe on her head, and a cornucopia in her hand. She had temples in Smyrna, Corinth, and Elis; but it was at Rome where she seems to have been more particularly worshipped, and where she had upwards of twenty shrines erected to her honour. There was a magnificent temple of Fortune at Præneste, now Palestrina, eighteen miles east from Rome. Here was the celebrated oracle called *Sortes Prænestinæ*, where the response was given by means of words written on pieces of wood, which were placed in a box, and having been taken out at random, were then united, when the priest declared the meaning of the answer. The first Mosaic pavement introduced into Italy was ordered by Sylla for this temple; and it is a curious fact that a very fine specimen is still seen at Palestrina, which may possibly be that to which we have alluded.

FORTUNATÆ INSULÆ, the name by which the Canary Islands were known to the ancients. The Carthaginians were no doubt acquainted with these islands at an early period, but it was the selfish nature of their policy to confine such knowledge to themselves, for the sake of the commercial advantages to be derived from it. It was not, therefore, till the fall of Carthage that the Greeks and Romans acquired any accurate information respecting the islands on the west coast of Libya. Statius Sebosus, the friend of Lutetius Catulus, consul 242 B.C., and who flourished in the time of the Cimbrian war, could not have been the first who made the discovery, though he was probably the first who gave a description of them to the public. Of this account we possess only a few notices by Pliny, who seems to have derived no information from any other quarter. Yet there must have been considerable intercourse with these islands, as we find that Sertorius, when flying before the superior force of the party of Sylla, was so charmed with the account of them he received from some sailors, that he was strongly tempted to take refuge there. The name seems at first to have been restricted to two, Convallis, the island of *Teneriffe*, and Planaria, now *Canaria*, from which the Canary Islands derive their name. Ptolemy extends the name to six islands. (Strab. i. 3; Plin. vi. 32; Plut. Sert. 9; See Minano, *Diccionario Geografico*, &c. Madrid, 1826.)

FORTUNE (*Τυχη*), a name which, amongst the ancients, seems to have denoted a principle by which things came to pass, without being necessitated thereto; but what that principle was, or whence it proceeded, they do not seem to have precisely considered. Hence their philosophers often intimate that men only conjured up the phantom of Fortune to hide their own ignorance; and that thus they call Fortune whatever befals a man without his knowing for what purpose. Hence Juvenal (*Sat.* x. ver. 366) affirms, there were men who made a deity of fortune.

> Nullum numen abest, si sit prudentia; sed te
> Nos facimus, Fortuna, deam, cæloque locamus.

According to the opinion of the heathens, therefore, Fortune was in reality only the occurrence of things in a sudden and unexpected manner, without any apparent cause or reason; so that the philosophical sense of the word coincides with what is commonly called *chance*.

But in religion the term had much greater force; for altars and temples in great numbers were consecrated to Fortune as a deity. This intimates that the heathens had personified, and even deified chance; conceiving it a sort of goddess who disposed at pleasure of the fate of men. Hence the invocation of Horace, *O diva, gratum quæ regis Antium*, in which he recommends Augustus, then preparing for a visit to Britain, to the protection of this divinity. From all this it may be inferred that the ancients at one time considered Fortune as a peremptory cause, operating in order to do good to some, and evil to others; and at another as a blind inconstant cause, without any view or determination at all. If, then, the word Fortune had no certain meaning even amongst those who erected altars in honour thereof, much less can it be ascertained what the term denotes in the minds of those who now use the word in their writings. They who would substitute the term *Providence* instead of that of *Fortune*, cannot give any tolerable sense to half the phrases in which the word occurs.

Horace paints the goddess as preceded by Necessity, holding nails and wedges in her hands, with a cramp-iron, and molten lead to fasten it, but rarely accompanied with Fidelity, unless when she abandons a family, in which case Fidelity never fails to depart with her, as well as friends. Fortune is disrespectfully spoken of by most of the Roman writers, and represented as blind, inconstant, unjust, and delighting in mischief (Ovid. *ad Liv.* ver. 52, ver. 374; Hor. lib. i. od. 34, ver. 26, lib. iii. od. 29, ver. 15; Statius, Theb. xii. ver. 505). However, they had a good as well as a bad fortune, a constant and an inconstant fortune, the latter of which was represented with wings, and a wheel beside her (Hor. lib. iii. od. 29, ver. 56). Juvenal alludes to a statue of Fortune, which exhibited her under a good character, as the patroness of the poor infants who were exposed by their parents in the streets (*Sat.* vi. ver. 605). The painters commonly represent her in a woman's habit, with a bandage over her eyes, to show that she acts without discernment; and standing on a wheel, to express her instability. The Romans, says Lactantius, represented Fortune with a cornucopia, and the helm of a ship, to show that she distributes riches, and directs the affairs of the world. In effect, it is by such characters that we see her represented upon so many medals, with the inscription, FORTUNA AVG. FORTUNA REDVX, FORTVNÆ AVG. or FORTUNÆ REDVCIS, and so on. Sometimes she is seen pointing at a globe before her feet, with a sceptre in one hand, and holding the cornucopia in the other.

The Romans had a male as well as a female Fortune which were objects of adoration; the *Fortuna virilis* being honoured by the men, and the *Fortuna muliebris* by the women. They appear to have derived the worship of Fortune from the Greeks under the reign of Servius Tullius, who dedicated to her the first temple in the public market-place. Nero also built a temple to Fortune. The Fortune worshipped at Antium was probably the most exalted of any amongst the Romans, if we may judge by the account which Horace gives us of the solemn processions that were made to her (Hor. lib. i. od. 35, ver. 22). But the most celebrated temple of Fortune was at Præneste; and Statius speaks of several, whom he calls the *Prænestinæ Sorores* (lib. i. Sylv. iii. ver. 80).

FORTUNE ISLANDS, two small islands in the Eastern Seas, one near the south-west coast of the island of Sumatra, in long. 90. 25. E. and lat. 1. 35. S.; the other near the north coast of the island of Celebes, in long. 123. 48. E. and lat. 0. 50. N.

FORUM, in Roman antiquity, a public place within the city of Rome, where causes were judicially tried, and orations delivered to the people.

FORUM was also used for a place of traffic, and answered to our market-place. These places were generally called *fora venalia*, in contradistinction to the former, which were called *fora civilia*.

The *fora civilia* were public courts of justice, commonly magnificent in themselves, and surrounded with porticoes and stately edifices. Of these, six were very remarkable: 1. *Forum Romanum;* 2. *Julianum;* 3. *Augustum;* 4. *Palladium;* 5. *Forum Trajani;* and, 6. *Forum Sallustii.* The *Forum Romanum* was the most noted, and is often styled simply *Forum*, by way of eminence. Here were the bar called *Rostra*, the *Comitium*, the sanctuary of *Saturn*, the temple of *Castor*, and other remarkable edifices. Of the *fora venalia*, or market-places, which were numerous, the chief were, the *forum boarium*, for oxen or beef; *suarium*, for swine; *pistorium*, for bread; *cupedinarium*, for dainties; and *olitorium*, for garden stuffs.

The Grecian αγοραι corresponded exactly with the Roman *fora*, being places where courts and markets were indiscriminately held. At Athens they had many *fora*, but the chief of these were the *old* and the *new*.

FORUM Indicere was the act of the prætor appointing the place in Rome where causes were to be tried. *Agere forum* denoted the bringing on causes out of Rome, in a Roman province, and was the same with *agere conventum.*

FOSS, or FOSSE, in *Fortification*, a ditch or moat. The word in French is formed from the participle *fossum*, of the Latin verb *fodio*, I dig.

Foss, *Fossa*, in *Anatomy*, a kind of cavity in a bone, with a large aperture, but no exit or perforation. When the aperture is very narrow it is called a *sinus.*

Foss is particularly used for the cavity or indenture in the back part of the neck.

FOSSA, in our ancient customs, was a ditch full of water, where women who had committed felony were drowned. *Nam et ipsi in omnibus tenementis suis omnem ab antiquo legalem habuere justitiam, videlicet ferrum, fossam, furcas, et similia.* In another sense it is used to signify a grave, as appears by these old verses:

> Hic jacent in fossa Bedæ Venerabilis ossa:
> Hic est fossatus, qui bis erat hic cathedratus.

Foss-Way was anciently one of the four great Roman highways of England, and, according to Camden, was so called because it was ditched on both sides, this having been the Roman method of making highways.

FOSSANO, a city of the province Cuneo, in the kingdom of Sardinia. It is situated on the river Stura, is fortified, and contains a cathedral, five other churches, six monasteries, two nunneries, and 14,000 inhabitants. It is a place of consideration, from its extensive silk manufactures, and from its tanneries. There is also much trade in wine, corn, hemp, and other products of the soil.

FOSSARII, in *Antiquity*, a kind of officers in the Eastern Church, whose business it was to inter the dead. Ciaconius relates that Constantine created nine hundred and fifty fossarii, whom he took out of the different colleges or companies of tradesmen; and he adds, that they were exempted from taxes, services, burdensome offices, and the like. Goar, in his notes on the Greek *Euchologion*, insinuates that the *fossarii* were established in the times of the apostles; and that the young men who carried off the body of Ananias, and those persons full of the fear of God who interred St Stephen, were of the number. St Jerome assures us that the *fossarii* held the first place amongst the clerks;

but he is to be understood of those clerks only who had the direction and superintendence of the interment of the devout.

FOSSIL, in *Natural History*, denotes in general every thing that is dug out of the earth, whether it be native thereto, as metals, stones, salts, earths, and other minerals, or extraneous, as the bones of animals, and the like.

Native fossils are substances found in the earth or on its surface, of a simple structure, exhibiting no appearances of organization, and included under the general names of simple and compound, earthy or metallic minerals. *Extraneous* fossils are bodies of the vegetable or animal kingdoms accidentally buried in the earth. Of the vegetable kingdom there are principally three kinds, trees or parts of them, herbaceous plants, and corals; and of the animal kingdom there are four kinds, sea shells, the teeth or bony palates and bones of fishes, complete fishes, and the bones of land animals. See MINERALOGY.

FOSTER, JAMES, a nonconformist divine, highly celebrated for his pulpit eloquence and erudition, was born at Exeter in the year 1697. At the age of five he was put to the free school of that city, where his progress in the acquisition of grammar was so rapid that his master boasted of him as the most eminent genius in his school. From this seminary he went to the academy where young men designed for being clergymen in the dissenting interest were educated, and here his progress was equally great. His apprehension was remarkably quick, his judgment solid, his memory retentive, his eloquence commanding, and his talents for argumentation truly admirable; but above all, his piety was genuine, and few men possessed candour, modesty, liberality, integrity, tenderness, and benevolence, in so remarkable a degree. He commenced preacher at the age of twenty-one, and was much admired where he occasionally officiated. But the doctrine of the Trinity, which was then much agitated in the west of England, did not accord with the notions of Mr Foster, and the honesty and openness of his heart would not suffer him to conceal his opinions, which, in fact, brought so much odium upon him from the orthodox party, that he retired to another scene of action. He became pastor of a congregation at Milborne-port, in Somersetshire; but as soon as his hearers became zealously attached to what was deemed the orthodox opinion, he retired to Ashwick, under the Mendip Hills, in the same county. In this asylum he preached to two congregations at a little distance from each other, the united contributions of which did not amount to L.15 per annum. In this state of poverty and obscurity he lived for some years, submitting patiently to the privations which were occasioned by his determined uprightness and sincerity. In 1720 he gave the world his *Essay on Fundamentals*, the design of which was to check an uncharitable and intolerant spirit, at that time extremely prevalent, by showing that the Trinitarian notion is not a fundamental article of Christianity, or made an express condition of salvation in the sacred Scriptures. A sermon accompanied this essay, entitled *The Resurrection of Christ proved and vindicated*, against the most important objections of the ancient Jews or modern Deists. From Ashwick, Foster removed to Trowbridge in Wiltshire, where his congregation did not usually exceed twenty or thirty persons.

By reading Dr Gale's treatise on infant baptism, he became a convert to the doctrine, that immersion is the true scriptural rite, and was accordingly soon afterwards baptized in London in conformity to that mode. This unreserved manner of adopting whatever his conscience believed to be truth, excluded him from almost every religious party amongst whom he might otherwise have expected preferment. But whilst he deliberated with himself whether he should abandon the ministry, and acquire the knowledge of some mechanical employment, Mr Robert Houlston received him into his house in the capacity of chaplain, and here his circle of acquaintances became wider and more respectable. In 1724 he was appointed to succeed Dr Gale in the Baptist congregation in Barbican, London. In 1728 he commenced a Sunday evening lecture in the Old Jewry, which he continued till within a short time of his death, with a degree of popularity which few dissenters at that time enjoyed. In 1732 appeared his work entitled The Usefulness, Truth, and Excellency of the Christian Revelation, defended against the objections contained in a late book, called *Christianity as old as the Creation*. In this reply Mr Foster exhibited no ordinary share of talents and ingenuity, and it was admired by the candid and judicious of every description. Dr Tindal, against whom it was written, is said to have always spoken of it with great respect. He published a volume of sermons in the year 1734, followed by three other volumes, the last of which appeared in 1744. At this time he was appointed successor to Dr Jeremiah Hunt, in the protestant congregation at Pinner's-hall. In 1746 he attended the Earl of Kilmarnock when under sentence of death for high treason, after which he published an octavo pamphlet, containing An Account of the Behaviour of the late Earl of Kilmarnock after his Sentence, and on the day of his Execution.

Foster received from Marischal College, Aberdeen, the degree of doctor in divinity, accompanied with handsome letters from the Principal and Professor Fordyce. "We beg," said the latter, "that you will be so good as to accept of the diploma, as a small mark of the sincere veneration we have for you, and of the sense we entertain of the eminent services you have done to the cause of liberty, religion, and virtue, by your writings as well as public instructions." The first volume in quarto of his *Discourses on all the principal Branches of Natural Religion and Social Virtue*, was published in the year 1749, and the second appeared in 1752. They were published by subscription; and to evince the high estimation in which his talents and virtues were held, two thousand names were contained in the list, many of them those of persons distinguished by their rank and literary abilities.

In the month of April 1750 he was seized with a violent distemper, from the effects of which he never thoroughly recovered; yet whilst at all able to officiate, he continued to preach till the beginning of 1752, when he had another attack, which seems to have been of a paralytic nature. After suffering for some time, he expired on the 5th of November, in the fifty-fifth year of his age. His private and public life were alike irreproachable. Foster, it appears, would have died in indigent circumstances, had it not been for the numerous subscriptions to his discourses on natural religion.

Besides the works above noticed, Dr Foster published three funeral sermons, one of which was intended for Mr Emlyn; together with a number of essays which appeared in the Old Whig.

FOSTER, *Samuel*, an English mathematician and professor of astronomy at Gresham College, was one of that learned association which met for cultivating the new philosophy, and which Charles II. established as the Royal Society. Mr Foster, however, died in 1652, before this incorporation took place; but he wrote a number of mathematical and astronomical treatises, particularly, 1. The Description and Use of a small portable Quadrant, for the more easy finding of the hour of azimuth, 1624, in 4to; 2. The Art of Dialling, 1638, in 4to; 3. *Posthuma Fosteri*, containing the description of a Ruler upon which are inscribed divers scales, 1652, in 4to; 4. Four

Treatises of Dialling, 1654, in 4to; 5. The Section altered, and other scales added, with the description and use thereof, 1661, in 4to; 6. Miscellanies, or Mathematical Lucubrations. Of the treatises in this collection some are written in Latin and others in English.

There were two other persons of this name who published mathematical works; William Foster, a disciple of Mr Oughtred, who taught in London; and Mark Foster, author of a treatise on trigonometry, who lived later than the former.

FOTHERGILL, Dr George, was born in Westmoreland in 1705, where his family had long possessed a competent estate, which had descended regularly for several generations. After receiving an academical education in Queen's College, Oxford, of which he became a fellow, he was, in 1751, elected principal of St Edmund's Hall, and presented to the vicarage of Brumley in Hampshire. Having been long afflicted with an asthma, he died of that disease in 1760, at the age of fifty-five. He was the author of a collection of sermons, in 2 vols. 8vo; the first consisting of occasional discourses, published by himself, and the second being printed from his manuscripts.

Fothergill, *Dr John*, an eminent physician, was born of Quaker parents, in 1712, at Carr End in Yorkshire, where his father, who had been a brewer at Knaresborough, lived retired on a small estate which he cultivated. The doctor was the second of five children, and received his education under the care of his grandfather Thomas Hough, a person of fortune in Cheshire (which gave him a predilection for that county), and at Sedbergh in Yorkshire. Having served his time to Mr Bartlett, an apothecary at Bradford, he removed to London, and became a pupil of Dr, afterwards Sir Edward, Wilmot, at St Thomas's Hospital. He then went to the university of Edinburgh for the purpose of studying physic, and there took his doctor's degree. From Edinburgh he went to Leyden, but after a short stay he returned to London, and began to practise about the year 1740, in a house in White-hart Court, Lombard Street, where he resided during the greater part of his life, and acquired most of his fortune. In 1746 he was admitted as a licentiate of the College of Physicians in London; and in 1754 as a fellow of that of Edinburgh, to which he was a considerable benefactor. He afterwards became a member of the Royal Medical Society at Paris, and a member of both the Royal and Antiquarian Societies. He continued his practice with uninterrupted success till within the two last years of his life, when an illness, which had been brought on by unremitting attention, obliged him to give up a considerable part of it. Besides his application to medical science, he had imbibed an early taste for natural history, and employed himself on conchology and smaller objects of botany. He had a very extensive practice, but he did not add to his art any great or important improvements. His pamphlet on the ulcerous sore throat is the best of his publications, but it owes much of its merit to the information of the late Dr Letherland. It was printed in the year 1748, on the re-appearance of that fatal disorder which in 1739 had carried off the two sons of Mr Pelham. In 1762 Dr Fothergill purchased an estate at Upton in Essex, and there formed a botanic garden. In 1766 he began, between Midsummer and Michaelmas, to withdraw from the excessive fatigue of his profession, and took no fees during this recess. For some time before his death he had been endeavouring to contrive a method of generating and preserving ice in the West Indies. He was the patron of Sidney Parkinson, and drew up the preface to his account of the voyage to the South Seas. At his expense also was made and printed an entirely new translation of the Bible, from the Hebrew and Greek originals, by Anthony Purver, a Quaker, in two volumes, 1764, folio; and also, in 1780, an edition of Bishop Percy's *Key to the New Testament*, adapted to the use of a seminary of young Quakers, at Ackworth, near Leeds in Yorkshire, founded in 1778 by the Society, who purchased, by a subscription, in which Dr Fothergill stood foremost, the house and an estate of thirty acres which the Foundling Hospital held there, but which they found inconvenient for their purpose. The doctor himself first projected this on the plan of a smaller institution of the same kind at Gildersomes, and endowed it handsomely by his will. It now contains above three hundred children of both sexes, who are clothed and instructed. Amongst the other beneficent schemes suggested by Dr Fothergill, were those of bringing fish to London by land carriage, which, though it did not in every respect succeed, certainly tended to destroy a supposed combination; and of rendering bread much cheaper, though equally wholesome, to the poor, by making it of one part of potatoes mixed with three parts of household flour. But all his public benefactions, his encouragement of science, and the instances of his attention to the health, police, and convenience of the metropolis, we cannot pretend to specify. The fortune which Dr Fothergill had acquired was great, amounting to about L.80,000. His business, when in full practice, was calculated at near L.7000 per annum. In the influenza of 1775 and 1776, he is said to have had sixty patients on his list daily, and his profits were estimated at L.8000 per annum. The disorder which hastened his death was a schirrus of the prostate gland, and an obstruction of the bladder. He died at his house in Harpur Street, in the month of December 1780, and his remains were interred in the Quakers' burying-ground at Winchmore Hill. The doctor by his will appointed that his shells and other pieces of natural history should be offered to Dr Hunter at L.500 under the valuation which he had ordered to be taken of them, and accordingly Dr Hunter bought them for L.1200. His drawings and collections in natural history were also offered to Sir Joseph Bankes at a valuation. His English portraits and prints, which had been purchased by him for eighty guineas, were bought by Mr Thane for two hundred guineas. His books were sold by public auction.

FOUGASSE, in the art of war, a small mine from six to eight feet under ground, and generally placed under the glacis, or in dry ditches. It is charged with sacks of powder covered with earth and stones, and, like larger mines, is fired by means of a saucisson.

FOUL, in nautical language, is used when a ship has been long untrimmed, so that grass weeds, or barnacles, grow on her sides under water. A rope is also foul when it is either tangled in itself, or hindered by another from running or being overhauled.

Foul imports also the running of one ship against another. This happens sometimes by the violence of the wind, and sometimes by the carelessness of the people on board, to ships in the same convoy, and to ships in port by means of others coming in. The damages occasioned by running foul are of the nature of those in which both parties must bear a share. They are usually made to fall half upon the sufferer, and half upon the vessel which did the injury; but in cases where it is evidently the fault of the master of the vessel, he alone must bear the damage.

FOUCHENGE, a town of Persia, in the province of Khorassan, twenty-five miles north of Herat. Long. 76. 29. E. Lat. 34. 50. N.

FOUL Islands, a cluster of small islands in the Indian Sea, near the north coast of the island of Flores. Long. 121. 22. E. Lat. 8. 9. S.

FOULA, or Fowla Island, one of the Zetland Isles, lying between six and seven leagues west from the main land. It is about three miles in length, narrow, and full of rough, steep, and bare rocks; one of which is so large, and runs up to such a height, that it may be clearly seen from Orkney. This solitary isle, it has been conjectured, is the Thule of Tacitus. It is pastoral, and maintains a few families.

FOULAHS, a people of Africa, who inhabit the confines of the Sahara, or Great Desert. The principal of the Foulah states is that within Sierra Leone, and of which Teembo is the capital.

FOUMART, a species of Mustela. See Mammalia.

FOUNDATION, in *Architecture*, is that part of a building which is under ground.

Foundation denotes also a donation or legacy, either in money or lands, for the maintenance and support of some community, hospital, school, or other institution.

FOUNDERY, or Foundry, the art of melting and casting all sorts of metal, such as brass, iron, &c. See Brass-making, and Iron-making; also the article Furnace.

Foundery of Small Works, or Casting in Sand. The sand commonly used for casting small works is at first of a pretty soft, yellowish, and clammy nature; but it being necessary to strew charcoal dust in the mould, it at length becomes of a quite black colour. The sand is worked over and over, on a board, with a roller and a sort of knife; and is placed over a trough to receive it, after it has by these means been sufficiently prepared.

This being done, the workmen take a wooden board of a length and breadth proportional to the things to be cast, and putting a ledge round it, they fill it with sand a little moistened, to make it duly cohere. They then take either wood or metal models of what they intend to cast, and apply them to the mould, and press them into the sand so as to leave their impression there. Along the middle of the mould is laid half a small brass cylinder, as the chief canal for the metal to run through, when melted, into the models or patterns; and from this chief canal are placed several others, which extend collaterally to each model or pattern placed in the frame. After this frame is finished, they take out the patterns, by first loosening them all round, that the sand may not give way; then they proceed to work the other half of the mould with the same patterns in just such another frame, only that it has pins, which, entering into holes corresponding to it in the other, make the two cavities of the pattern fall exactly on each other.

The frame, thus moulded, is carried to the melter, who, after extending the chief canal of the counterpart, and adding the cross canals to the several models in both, and strewing mill dust over them, dries them in a kind of oven prepared for the purpose. Both parts of the mould being dry, they are joined together by means of the pins; and to prevent them giving way, by reason of the melted metal passing through the chief cylindrical canal, they are screwed or wedged up like a kind of press.

Whilst the moulds are thus preparing, the metal is fusing in a crucible of a size proportional to the quantity of metal intended to be cast. When the moulds have cooled, the frames are unscrewed or unwedged, and the cast work taken out of the sand, which sand is worked over again for other casting.

Foundery of Statues. The casting of statues depends on the due preparation of the pit, the core, the wax, the outer mould, the inferior furnace to melt off the wax, and the upper to fuse the metal.

The pit is a hole dug in a dry place, something deeper than the intended figure, and made according to the prominence of certain parts of it. The inside of the pit is commonly lined with stone or brick; but when the figure is very large, they sometimes work on the ground, and raise a proper fence to resist the impulsion of the melted metal. The inner mould, or core, is a rude mass, to which is given the intended attitude and contours. It is raised on an iron grating strong enough to sustain it, and is strengthened within by several bars of iron. It is generally made either of potters' clay mixed with hair and horse dung, or of plaster of Paris mixed with brick dust. The use of the core is to support the wax and the shell, and lessen the weight of the metal. The iron bars and the core are taken out of the brass figure through an aperture left in it for that purpose, which is soldered up afterwards. It is necessary to leave some of the iron bars of the core, which contribute to the steadiness of the projecting part, within the brass figure. The wax is a representation of the intended statue. If it be a piece of sculpture, the wax should be all from the hand of the sculptor himself, who usually forms it on the core; though it may be wrought separately in cavities, moulded on a model, and afterwards arranged on the ribs of iron over the grating, filling the vacant space in the middle with liquid plaster and brick dust, by which means the inner core is proportioned as the sculptor carries on the wax. When the wax, which is of the intended thickness of the metal, is finished, small waxen tubes perpendicular to it from top to bottom are filled, to serve both as canals for the conveyance of the metal to all parts of the work, and as vent-holes to give passage to the air, which would otherwise occasion great disorder when the hot metal came to encompass it.

The work being brought thus far, must be covered with its shell, which is a kind of crust laid over the wax, and which being of a soft matter, easily receives the impression of every part, which is afterwards communicated to the metal upon its taking the place of the wax, between the shell and the mould. The matter of this outer mould is varied according as different layers are applied. The first is generally a composition of clay, and old white crucibles well ground and sifted, and mixed up with water to the consistence of a colour fit for painting; and it is applied with a pencil, by means of which it is laid on seven or eight times successively. For the second impression horse dung and natural earth are added to the former composition; but for the third impression only horse dung and earth are used. Lastly, the shell is finished by laying on several more impressions of this last matter, made very thick with the hand. The shell, thus finished, is secured by several iron girths bound round it, at about half a foot distant from each other, and fastened at the bottom to the grating under the statue, and at top to a circle of iron where they all terminate.

If the statue be so large that it would not be easy to move the moulds with safety, these must be wrought on the spot where it is to be cast. This is performed in two ways. In the first place, a square hole is dug in the ground, much larger than the mould to be made therein, and its inside is lined with walls of freestone or brick. At the bottom is made a hole of the same materials, with a kind of furnace, having its aperture outwards; and in this is a fire made, to dry the mould, and afterwards melt the wax. Over this furnace is placed the grating, and upon this the mould, formed as above. Lastly, at one of the edges of the square pit is made another large furnace, to melt the metal. In the other way, it is sufficient to work the mould above ground, but with the precaution of a furnace and grating underneath. When finished, four walls are run around it, and by its side a melting furnace is prepared. For the rest, the method is the same in both cases. The mould being finished, and enclosed as described, whether below ground or above it, a moderate

Foundery.

fire is lighted in the furnace under it, and the whole covered with planks, that the wax may melt gently down, and run out at pipes contrived for that purpose at the foot of the mould, which are afterwards exactly closed with earth, as soon as the wax is all carried off. When this is done, the whole is filled up with bricks thrown in at random, and the fire in the furnace augmented, until both the bricks and mould become red hot. The fire is then extinguished, and every thing being cold again, the bricks are taken out, and their place filled up with earth, moistened, and beaten a little at the top of the mould, in order to render it the firmer. These preparatory measures being duly taken, there remains nothing but to melt the metal, and run it into the mould. This is done by means of the furnace above described, which is commonly made in the form of an oven with three apertures, one to put in the wood, another for a vent, and a third to run the metal out at. From this last aperture, which is kept very close whilst the metal is in fusion, a small tube is laid, by which the molten metal is conveyed into a large earthen basin, over the mould, into the bottom of which all the large branches of the jets or casts, which are to convey the metal into the different parts of the mould, are inserted.

These casts or jets are all terminated with a kind of plugs, which are kept close, so that, upon opening the furnace, the brass, which rushes out with violence, may not enter any of them till the bason be full enough of matter to run into them all at once; upon which occasion they pull out the plugs, which are long iron rods with a head at one end, capable of filling the whole diameter of each tube. The whole of the furnace is then opened with a long piece of iron fitted at the end of each pole, and the mould filled in an instant. This completes the work in relation to the casting part; the rest is the sculptor's or carver's business, who, taking the figure out of the mould and earth with which it is encompassed, saws off the jets with which it appears covered over, and finishes it with chisels, gravers, puncheons, and other instruments.

Foundery of Bells. The metal for casting bells, it is to be observed, is different from that employed for casting statues; there being no tin in the statue metal, whereas in the bell metal there is a fifth, and sometimes more.

The dimensions of the core and the wax for bells, especially a chime, are not left to chance, but must be measured upon a scale, or diapason, which gives the height, the aperture, and the thickness, necessary for the several tones required. It is on the wax that the several mouldings and other ornaments and inscriptions, to be represented in relief on the outside of the bell, are formed. The clapper or tongue is not properly part of the bell, but is furnished from other hands. In Europe it is usually of iron, with a large knob at the extremity; and is suspended in the middle of the bell. In China it is only a huge wooden mallet, struck by the hand against the bell; and hence they can have but little of that consonance so much admired in some of our chimes of bells. The Chinese have a method of increasing the sound of their bells, by leaving a hole under the cannon; but this our bell-founders would reckon a defect.

The proportions of our bells differ very much from those of the Chinese. In ours, the modern proportions are, to make the diameter fifteen times the thickness of the brim, and the height twelve times. The parts of a bell are, first, the sounding bow, terminated by an inferior circle, which grows thinner and thinner; secondly, the brim, or that part of a bell whereon the clapper strikes, and which is thicker than the rest; thirdly, the outward sinking of the middle of the bell, or the point under which it grows wider to the brim; fourthly, the waist or furniture, and the part that grows wider and thicker quite to the brim; fifthly, the upper vase, or that part which is above the waist; sixthly, the pallet, which supports the staple of the clapper within; and, seventhly, the bent and hollowed branches of metal uniting with the cannons, to receive the iron keys, by which the bell is hung up to the beam, and which forms its support and counterpoise when rung out.

Foundery || Fountain-tree.

Without entering into the details of the operations, we may state, that the business of bell foundery is reducible to three heads; first, the proportion of a bell; secondly, the forming of the mould; and, thirdly, the melting of the metal.

Foundery of Great Guns and Mortar Pieces. See Cannon-Making.

Letter Foundery, or *Casting of Printing Letters.* See Printing and Type-Making.

FOUNT, or Font, among printers, a set or quantity of characters or letters of each kind, cast by a letter-founder, and sorted. Thus, we say, a founder has cast a fount of pica, of english, and of pearl; meaning that he has cast a set of characters of these kinds.

A complete fount not only includes the running letters, but also large and small capitals, single letters, double letters, points, commas, lines, and numeral characters. See Printing and Type-Making.

FOUNTAIN, a spring or source of water rising out of the earth. Amongst the ancients, fountains were generally esteemed sacred; but some were held to be so in a more particular manner than others. The good effects resulting from cold baths gave springs and rivers this high reputation; for their salutary influence was supposed to proceed from some presiding deity. Particular reasons, however, occasioned some to be held in much greater veneration than others. It was customary to throw little pieces of money into those springs, lakes, or rivers, which were esteemed sacred, in order to render the presiding divinities propitious; as the touch of a naked body was supposed to pollute their hallowed waters. For the phenomena, theory, and origin of fountains or springs, see Spring.

Fountain-Tree, a very extraordinary vegetable, which grows in one of the Canary Islands, and is likewise said to exist in some other places, and which distils water from its leaves in such plenty as to answer all the purposes of the inhabitants who live near it. Of this tree we have the following account in Glasse's *History of the Canary Islands*:—"There are only three fountains of water in the whole island of Hierro, wherein the fountain-tree grows. One of these fountains is called *Acof*, which, in the language of the ancient inhabitants, signifies *river*; a name, however, which does not seem to have been given it on account of its yielding much water, for in that respect it hardly deserves the name of a fountain. More to the northward is another, called *Hapio*; and, in the middle of the island is a spring, yielding a stream about the thickness of a man's finger. This last was discovered in the year 1565, and is called the fountain of Antonio Hernandez. On account of the scarcity of water, the sheep, goats, and swine here do not drink in the summer, but are taught to dig up the roots of fern, and chew them to quench their thirst. The great cattle are watered at those fountains, and at a place where water distils from the leaves of a tree. Many writers have made mention of this famous tree, some in such a manner as to make it appear miraculous; others again deny the existence of any such tree, among whom is Father Feyjoo, a modern Spanish author, in his Teatro Critico. But he, and those who agree with him in this matter, are as much mistaken as those who would make it appear to be miraculous. This is the only island of all the Canaries which I have not been in; but I have sailed with natives of Hierro, who, when questioned about the existence of this tree, answered in the affirmative."

FOUR BOROUGHS' COURT, an ancient Scottish court, so called because composed of delegates from four royal burghs; originally the burghs of Edinburgh, Stirling, Berwick, and Roxburgh; but from the year 1348, when the two last burghs were in the hands of the English, the burghs of Edinburgh, Stirling, Lanark, and Linlithgow. These delegates were assembled yearly at Haddington, before the Lord Chamberlain of Scotland, and formed for appeals from the burgh courts and chamberlain ayres, a court which was to the inhabitants of the burghs what the high court of parliament was to the other inhabitants of the kingdom, the highest and ultimate court of appeal.

In 1405, when the regent, Robert duke of Albany, uncle to King James I., was lord chamberlain, a court of the four burghs was held at Stirling, where it was resolved that deputies from the royal burghs south of the Spey should convene yearly with the four burghs, to consider and conclude on all matters affecting the common weal of all the royal burghs. This convention, though at first assembled with the court of four burghs, does not appear to have ever formed a constituent part of the latter assembly, and it seems also soon to have disregarded both the place and time of its meeting; for in 1487 its constitution was materially improved, representatives from all the royal burghs, " baith south and north," being by a statute of that year appointed to meet in convention yearly at Inverkeithing, " there to commoun and treate upon the weilfare of merchandice, the gude rule and statutes for the common profite of burrowes, and to provide for remeid upon the skaith and injuries sustained within the burrowes."

The chamberlain ayres, which had long been regarded by the nation as a grievance demanding immediate reformation, were thus substantially superseded, and accordingly soon afterwards fell into disuse. The court of four boroughs continued somewhat longer; but on the institution of the court of session, which was vested with a universal civil jurisdiction, its judicial functions were swallowed up, and it likewise expired. The office of lord chamberlain itself also, falling into the hands of the nobility and court favourites, ceased to be exercised; and his place in the convention came to be occupied by the Lord Provost of Edinburgh, who, though not a member, is the constant preses of the convention. The origin of this last circumstance, hitherto, we believe, unexplained by our writers, seems to be this. The convention was, by the statute above mentioned, appointed to meet at Inverkeithing. This, however, it did not long continue to do; but, like the court of four burghs and the other supreme courts of the kingdom, removed to Edinburgh as early as the time of Alexander Lord Home, who was great chamberlain from 1488 to 1517; and as that individual was at one time both lord provost of Edinburgh and great chamberlain of Scotland, and also, as it seems, the last in the latter office who exercised its duties in person, hence, no doubt, arose the practice of the lord provost of Edinburgh being the permanent preses, and the town-clerk of Edinburgh the perpetual clerk, of the convention. This civic parliament has continued till the present time. By stat. 1607, c. 6, letters of horning were allowed to issue on all its acts and decrees betwixt burgh and burgh, and burgesses of free burghs, on a simple charge of ten days.

FOUR SADDLE ISLAND, an island in the Mergui Archipelago, about six miles in circumference, and separated by a narrow strait from the island of St Susannah. Lat. 10. 27. N.

FOUR CRAG'S ISLAND, a low flat island, of a quadrangular figure, on the south-west coast of New Holland. Long. 137. E. Lat. 36. 26. S.

FOURCHEE, or **FOURCHY**, in *Heraldry*, an appellation given to a cross forked at the end. See HERALDRY.

FOURCROY, ANTONY FRANCIS DE, a celebrated chemist and physician, born at Paris on the 15th June 1755, was the son of John Michael de Fourcroy, by his marriage with Jane Laugier. His family had been long established in the capital; several of them had been distinguished at the bar, and Fourcroy de Ramcourt was well known as an engineer of considerable talent, and a member of the Academy of Sciences.

His father was an apothecary attached to the household of the Duke of Orleans, and was a great sufferer by the abolition of places of this kind, which was procured by the corporation of apothecaries, some time before the Revolution. Young Fourcroy was sent to the college of Harcourt, but made no progress in his learning there, and underwent great hardships, from the cruelty of an unjust master. He was afterwards obliged to subsist by his labour in copying, and by taking pupils as a writing master. He was, however, fortunate in the patronage and assistance of Vicq d'Azyr, who had been a friend of his father, and under whose auspices he resolved to study physic; obtaining his support in the mean time by giving his assistance to richer persons than himself in their literary labours, and by a few translations, for which he was very ill paid. When he had gone through the regular course of study, he became a candidate for a gratuitous diploma, upon a foundation established by Dr Diest; but he failed of success, from a party quarrel. His own party, however, which was that of Vicq d'Azyr, indemnified him for the loss, by making a collection to discharge the fees, amounting to about L.250; but the highest degree, that of doctor regent, was still refused him; and he was therefore incapable of holding a professorship under the Parisian faculty of physic. He resolved to apply himself to science as the readiest way of acquiring medical reputation; but he seems to have been little known, at any time of his life, as a practical physician. The determination, however, like that of the countryman in the fable, was still a beneficial one; and though he failed of discovering the golden treasure for which he dug, he profited by the increased fertility of the soil, and by the abundant fruits which it bore him.

In natural history he soon distinguished himself as a pupil worthy of Geoffroy, by an entomological publication; and in anatomy, by his description of the tendons and their sheaths, which appears to have procured his admission into the Academy of Sciences in 1785. He stood at first in the capacity of an anatomist, though he was afterwards removed to the section of chemistry. His favourite pursuit, however, from the beginning, was chemistry; and in this he derived considerable assistance from Bucquet, who was then a professor in great esteem; and having once undertaken to deliver a lecture in his place, on occasion of a temporary indisposition of Bucquet, though wholly unprepared, he found himself capable of speaking for two hours with great fluency, to the delight and astonishment of his audience. The reputation of Bucquet was soon transferred to Fourcroy; and he was enabled, by an advantageous marriage, to purchase the apparatus of his predecessor, and to succeed to his lectures.

In 1784, upon the death of Macquer, then professor of chemistry in the Royal Garden, the Count de Buffon found the claims of Fourcroy so strong, that he thought it right to appoint him to the vacant chair, though no less a chemist than Lavoisier was a rival candidate; the competition not being wholly decided either by talent or by depth of learning, but probably, in a great measure, by the reputation in the art of teaching which Fourcroy had already acquired. His success in this new situation was brilliant and universal; and he continued for twenty-five years to absorb the whole attention of a numerous audience, by his eloquence, and by the perspicuity of his mode of explaining some of the most important novelties that have ever appeared in any age. The science which he taught was then making its most rapid progress. It was then that Bergman and Scheele had introduced into analytical chemistry a precision almost geometrical; that Priestley had discovered the aëriform elements of the animal and vegetable world; that Black and Wilcke had methodised the phenomena of heat; that Cavendish had discovered the composition of water and of the nitric acid; that Monge had repeated and extended his experiments; and that Lavoisier had reduced the whole of chemistry to a uniform system, which, though founded on a generalization somewhat too hasty, has still been of important service to the science, by concentrating the attention of the philosophic reasoner on various classes of phenomena, which could not so easily have been comprehended in one view, without the aid of some such hypothesis. M. de Fourcroy was particularly happy in his tact of perceiving whether or not all his audience were fully in possession of the ideas he wished to communicate to them, and he was never tired of explaining himself, till he was satisfied that he had said enough. His manner was energetic, and such as an Englishman might perhaps have thought pompous and affected; but we must recollect that there is no fixed standard of propriety in matters of taste, and that, as the common conversation of the French is naturally accompanied with more of emphasis and gesture than our own, it is very possible that, without any greater proportional exaggeration than is introduced in similar cases in Great Britain, an actor, a lecturer, or a preacher, may exhibit what to us would appear a caricature, while it only affects his own countrymen as a natural, though impressive, style of public speaking. The chemical amphitheatre of the Public Garden was crowded by students from all countries, and from all quarters of the globe, some prompted to visit Paris by their own love of learning only, some assisted in their pursuits by their respective governments; and it was twice in succession necessary to provide more extensive accommodations for the overflowing numbers that sought for admittance.

M. de Fourcroy's political life, though not unsuccessful, seems to have contributed less materially to his happiness than his scientific career. He was chosen a supplementary member of the National Convention, and entered on the functions of the office in the dreadful period of 1793. He had, however, the wisdom to refrain from employing the eloquence that he possessed under circumstances so dangerous, and he almost entirely confined his exertions to some attempts to soften the cruel tyranny of the times. Darcet was one of the destined victims that he had the good fortune to save; but he soon found it too dangerous to persist in such interferences. M. Cuvier, however, very fully acquits him of any approbation of the judicial murders which were committed, and of any connivance at such proceedings as it might have been possible for him to avert; declaring, that if, upon the strictest inquiry, he could have discovered that there was the least foundation for charging him with having been indifferent to the fate of his great rival Lavoisier, no consideration on earth could have induced him to become the biographer of a person so odious and contemptible. It was at a later period that Fourcroy acquired some little influence as a director of the public instruction; and in this capacity he had great scope for the exertion of his talents, in the re-establishment of the many public institutions connected with science, which the madness of the Revolution had destroyed. The *Ecole de Médécine* was one of the first that was restored; but the name of Médécine seeming to carry with it too much of respect and authority for the levelling spirit of the day, the new institution was at first called *Ecole de Santé*. M. de Fourcroy was also very essentially concerned in the organization of the *Ecole Polytechnique*, as well as of the central schools of the departments, and of the *Normal* schools of Paris; nor was he an indifferent spectator of the establishment of the *Institute*, which was at first intended to be as much immediately subservient to public instruction, as to making known the results of private study. He had also considerable influence in obtaining the adoption of a law calculated greatly to facilitate the formation of a museum of natural history on a magnificent scale. If, in the pursuit of these objects, he sometimes appeared to forget the dignity of language most appropriate to his subject, it must be remembered that he lived in times when the choice of expressions was by no means at the option of the speaker. He was once denounced by the Jacobins, merely for his silence in the assembly; but he excused himself, by pleading the absolute necessity of applying himself to chemical pursuits for the support of his family.

In 1798 his duties as a senator were terminated; but he was made a counsellor of state under the consular government, and again employed in the department of public instruction, with less liberty to pursue his own ideas than before, but with more effectual means of attaining the objects of his appointment. In this capacity he directed, in the course of five years, the establishment of twelve schools of law, and of more than thirty lyceums, afterwards called royal colleges, and three hundred elementary schools; exhibiting, in the performance of this laborious duty, the greatest possible judgment and attention in overcoming the local difficulties which perpetually occurred in the details of the undertaking, and depending on none but himself for the whole of the required arrangements. He conducted himself with great impartiality in his choice of the persons to be employed, though he sometimes found himself obliged to pay a certain degree of deference to the arbitrary power under which he acted, or even to his own political connexions. Remembering the difficulties which he had himself encountered in the early part of his career, he was particularly kind and benevolent in his intercourse with those young men to whom he was the dispenser of public munificence, in admitting them to a gratuitous education.

The great number and extent of M. de Fourcroy's scientific labours may be considered as paramount to a more immediate participation in the discovery of some of the new facts which changed the aspect of the science of chemistry. His ideas were, however, often rather enlarged than profound; and he was not uncommonly somewhat too precipitate in his conclusions; but he was generally methodical in the mode of conducting his researches, and clear in relating their results. His pursuits and projects were sometimes varied a little capriciously, though he prosecuted them all with equal warmth and eloquence. He was too much the slave of public opinion for his own comfort; and even the slightest expression of censure that occurred in private society, or the most unimportant criticism that appeared in a periodical work, became a heavy misfortune to him, and deprived him of his tranquillity for a considerable time. But the desire of universal approbation acted upon him as a strong incentive to continued exertion; and, amongst all his political and official labours, he continued his experiments, his memoirs, and his lectures, with as much eagerness as if they had constituted his whole occupation. His nerves seem ultimately to have suffered by his unremitting application, and he became subject to palpitations, which, as he was well aware, rendered the duration of his life extremely precarious. At last, on the 16th of December 1809, at the age of fifty-four, as he was signing some dispatches, he exclaimed suddenly, "I am dead;" and his words were true. It happened, that on that day his family were about to assemble for the celebration of an anniversary in which they were particularly interested; the assembly actually met, though only to mourn his loss; and their disappointment was rendered the greater, upon the receipt of some distinguished marks of the imperial favour, which arrived too late to be of any use to his spirits or to his health, but which would have been of the more value to him, as he had before been passed over, when some of his colleagues had received considerable gratifications. He had, however, been made a count of the empire, and a commander of the legion of honour, in addition to his various literary and scientific titles; and he must have had the heartfelt satisfaction of reflecting, that he had been of use to the promotion of knowledge by his experiments and his writings; to his country by the public institutions which he had established; and to many deserving individuals by the benefits which he had bestowed on them, without the remorse of having done injury to any one.

He left a son by his first marriage with Mlle. Bettinger, the Count de Fourcroy, an officer of artillery, who was afterwards killed in the campaign of 1813 in Saxony, and a daughter, Mad. Foucaud. By his second marriage with Mad. Belleville, the widow of M. de Wailly, he had no children. His two maiden sisters also survived him, though by no means in a state of affluence; but they received great kindness from his friend and assistant M. Vauquelin. His place at the Institute was very ably filled by M. Thénard; M. Laugier succeeded him at the Museum, and M. Gay Lussac at the Ecole Polytechnique.

The chief of M. de Fourcroy's separate publications are, 1. *Essai sur les Maladies des Artisans*, 12. Paris, 1777, translated from Ramazzini. 2. *Analyse Chimique de l'Eau Sulfureuse d'Enghien*, par Fourcroy et Laporte, 8vo, 1778, applying the recent discoveries on the nature of gases to the contents of this water. 3. *Leçons Elémentaires d'Histoire Naturelle et de Chimie*, 2 vols. 8vo, 1782; 5 vols. 8vo, 1789, 1794; afterwards translated by Nicholson. 4. *Mémoires et Observations de Chimie*, 8vo, 1784; a collection of memoirs intended as a sequel to the elements. Most of these had been read to the academy before the author was a member, and were destined for the *Mémoires des Savans Etrangers*. They relate to the metallic carbonates, to detonations, to tests for water, to combustions in a stream of oxygen, and to the properties of several saline and metallic substances, with a useful introduction on the mode of conducting chemical experiments. 5. An edition of the *Entomologia Parisiensis of Geoffroy*, 2 vols. 12mo, 1780; extracted from Geoffroy's larger work, with the addition of two hundred and fifty new species. 6. *L'Art de connaitre et d'employer les Médicamens dans les Maladies*, 2 vols. 8vo, 1785. 7. *Méthode de Nomenclature Chimique*, par de Morveau, Lavoisier, Berthollet, et De Fourcroy, 8vo, 1787. 8. *Essai sur le Phlogistique et les Acides*, 8vo, 1788; from the English of Kirwan. 9. *La Médécine éclairée par les Sciences Physiques*, 4 vols. 8vo, 1791, 1792; a collection of papers, with some original essays by the editor. 10. *Philosophie Chimique, ou Vérités Fondamentales de la Chimie Moderne*, 1792, 1796, 1800. Reviewed by Deyeux, *Ann. de Chim.* lvi.; a work which has been translated into almost every European language, including modern Greek. 11. *Procédés pour extraire la Soude du Sel Marin*, 4to, 1795. 12. *Système de Connaisances Chimiques*, 10 vols. 8vo, 5 vols. 4to, 1800. This vast collection of chemical information was written from beginning to end in the space of eighteen months, during an interval of leisure from public business. *Rev. Ann. Ch.* xxxvi. xxxvii. Translated by Nicholson. 13. *Tableaux Synoptiques de Chimie*, fol. 1800, 1805. 14. *Abrégé de Chimie, pour l'usage des écoles vétérinaires*. 15. *Chimie pour les Dames*, in the *Bibliothèque des Dames*.

Besides his separate works, M. de Fourcroy was the author of more than a hundred and sixty memoirs, printed in different publications, the principal of which it will be sufficient to enumerate in a very cursory manner, adding a few of Dr Thomson's able criticisms on the respective articles. The most important of his later researches were published jointly in his own name and in that of his pupil Vauquelin; and it is supposed that the processes were generally conducted and often suggested by Vauquelin, but that the investigations were set on foot and directed, and the results described and methodized, with inferences and theoretical reasoning, by Fourcroy.

16. In the *Memoirs of the Academy of Sciences* we find an *Anatomical History of the Tendons and their Mucous Capsules*, 1785, 1786, 1787. 17. *On the Smoking Oil of Vitriol of Saxony, and the Concrete Salt obtained from it*, 1785; modifications of the sulphurous acid. 18. *On Hepatic Gas*, 1786. 19. *Report on a Sand from Peru containing Copper*. 20. *On Azote, and its production in animals*, 1787. 21. *On detecting Lead in Wines*, 1787. 22. *On Combustions in the Oxymuriatic Acid*, 1788. 23. *On Metals precipitated by Ammonia*, 1788. 24. *Experiments on Animal Substances, made at the Lyceum*, 1789. 25. *On a Liver changed by putrefaction*, 1789. 26. *On the Colours derived by Vegetables from Oxygen*, 1789. 27. *On an Ore of Lead from Roziers*, 1789. 28. *On the Sulfate of Mercury, and on Triple Ammoniacal Salts*, 1790. 29. *On the Formation of the Nitric Acid by the Action of the Oxyd of Mercury on Ammonia*, 1790. 30. *On the Combustion of Hydrogen in close vessels*, by Fourcroy, Vauquelin, and Séguin, 1790. 31. *On Barita and Strontia*, Mém. Inst. vol. ii. 1797. 32. *On Phosphate of Lime and on Phosphorus*, ib. 33. *On the Urinary Secretion in Horses and in the Human Subject*, ib. 34–36. *On Urinary Calculi, with two more Memoirs on the Secretion*, iv. 1803. 37. *On the Nitrous Oxyd*, by Fourcroy, Vauquelin, and Thénard, vi. 1806. 38. *On Cow's Milk*, ib. 39. *On the Guano, used as a Manure in the South Sea Islands*, ib. 40. *On Tabasheer*, ib. 41. *On the Chemical Nature of Carious Wheat*, ib.; the change is supposed to depend on an alteration and depravation of the gluten. 42. *On a Detonating Substance obtained from Indigo*, ib. 43. *On Animal Substances treated by Nitric Acid*, ib. 44. 45. *Two Memoirs on Crude Platina and a new Metal found with it*. 46. *On the effects of Germination and Fermentation on Corn and Pulse*, vii. 1801. 47. In the *Memoirs of the Royal Society of Medicine for* 1782–83–84, Par. 1787, we find a valuable memoir *On the Muriate of Lime*, p. 267, which the author seems to have been one of the first to introduce in such cases as had usually been benefited by sea water. 48. *On Morbid Changes in some of the Animal Fluids*, p. 488. 49. *On the Nature of Muscular Fibres, and on the Seat of Irritability;* showing the analogy of muscular fibre to the coagulable lymph of the blood, and observing that Bordeu had very properly called the blood a fluid muscle.

Many of these earlier papers have also been printed in the *Annales de Chimie*, but they are sometimes altered, and they are mixed with others which are original. 50. *On Azote* (20), vol. i. (1789). This memoir exhibits no very favourable specimen of the author's accuracy; for he asserts in it that pure azote turns vegetable blues to green, and that it may be obtained by means of a low heat, from the oxide of manganese. 51. *On the Gas in the Air Vessels of the Carp*. 52. *On a Morbid Change in the Blood*, ib.; exuding from the face. 53. *On detecting Lead in*

Wine (21), ib. 54. 55. *On two Ores of Lead*, ii.; containing the arseniate and the phosphate. 56. *On the action of Oxyds on Ammonia*, ib.; particularly those of manganese, mercury, and tin. 57. *On the Salts of Magnesia*, ib. 58. *On a Change in the Liver after Death* (25), iii. 59. *On Biliary Calculi*, ib.; describing the adipocere of these substances. 60. *On the Albumen of Vegetables*, ib.; more properly distinguished by Proust under the name of gluten. 61. *On the Carbonate of Barita of Alston Moor*, iv. 62. *On the Medical Properties of Oxygen*, ib. 63. *On the Triple Salts of Ammonia and Magnesia*, ib.; an elaborate and interesting paper. 34. *On Combustions in Oxymuriatic Acid Gas*, ib. 65. *On the effect of Oxygen in colouring Vegetables, and on the preparation of Solid Pigments*, v. 66. *On the Changes observed in the Cemetery of the Innocents*, ib. Fourcroy had been appointed, together with Thouret, to superintend the removal of these remains to a remoter spot, and observed that the muscular parts were often slowly changed into a substance nearly resembling spermaceti. 67. *On a Black Sand from St Domingo*, vi. 68. *On the Water of Enghein*, (2), ib. 69. *Discoveries in Animal and Vegetable Chemistry*, ib. 70. *On the Formation of the Nitric Acid from the Action of the Oxyd of Mercury on Ammonia*, (29), ib. 71. *On the Culture of Cloves in the Isle of Bourbon*, vii. 72. *Experiments on Animal Substances, made at the Lyceum in* 1790, (24), ib. 73. *Second Memoir on the Substances found in the Cemetery.* 74. *On the Cinchona of St Domingo*, viii. x.; a very valuable analysis of a species of bark officially referred to his examination. 75. *On the Combustion of Hydrogen*, (30), viii. 76. *Report on Loyser's Art de la Verrerie*, ix. 77. *On Bell Metal*, ib. The principal object of this paper is to discover a ready mode of converting the spoils of the churches into copper coin, by fully oxidating a part of the alloy, and fusing the remainder with it; the whole of the tin becomes oxidated, and the copper is melted out in a state of purity. 78. *On Tears and Mucus*, x.; a valuable investigation of the nature of the substances most generally diffused in the animal fluids. 79. *On the Sulfate of Mercury, and its combination with Ammonia*, ib.; a paper containing several new facts, though mixed with some inconclusive reasoning. 80. *On the Refinement of Saltpetre*, xi. 81. *On the Juice which furnishes Elastic Gum*, ib. 82. *Note on the Decomposition of the Carbonic Acid Gas, effected by Mr Tennant*, xii. 83. *On Triple Salts*, xiii. 84. *On Animal Concretions*, from the *Dictionnaire Encyclopédique.* 85. *On the Brain*, xvi. 86. *Report on some Artificial Pencils*, xx. 87. *Extract of a Memoir on Hydrocarbonous Gas, and on the supposed Combustion of Azote*, xxi.; showing that though phosphorus is soluble in azote, it is only so far burned in it as some particles of oxygen happen to be present. 88. *On Detonations by Percussion*, ib. 89. *Extract of a Memoir of Proust on Odoriferous Substances*, ib.: M. de Fourcroy proved the non-existence of any separate principle deserving the name of aroma, and showed that odorous substances in general were volatilized without any change of their nature or separation of their parts. 90. *On obtaining Pure Barita*, ib.; an elegant and effectual process. 91. *On the Union of Chemistry with Pharmacy*, ib. 92. *On Vitality, and on Humboldt's Experiments*, xxii. 93. *On the Action of the Sulfuric Acid on Vegetable and Animal Substances*, xxiii. 94. *On the Formation of the Sulfuric Ether*, ib. This paper seems to make it probable that the attraction of the acid for water tends to facilitate the formation of the ether in this instance, though the same theory cannot be applied to the action of the other acids on alcohol. 95. *On the Sulfurous Acid*, xxiv. 96. *Report on some Colours for Porcelain*, xxv. 97. *Letter to Humboldt on the Chemistry of Life*, xxvii. 98. *Examination of Dr Pearson's Experiments on Calculi*, ib.; with a general request to medical men, soliciting the communication of specimens. 99. *On Pneumatic Medicine*, xxviii. 100. *On the Experiments of Mayow*, from the *Dictionnaire Encyclopédique*, xxix. 101. *Novelties from Egypt*, ib. 102. *On Congelation by Artificial Cold*, ib. 102. *Letter to Giobert on Calculi*, xxx. 103. *Notice of Venténat's Vegetable System*, ib. This botanist has given to an elegant genus of plants the name of Furcroea, in compliment to the merits of our author in natural history. 104. *On the Chemical and Medical History of the Urinary Secretion*, xxxi. xxxii.; finding some of the peculiar substances which occur in the human subject to be identical with some of the contents of the excretions of birds, though they are wanting in the same fluid formed by quadrupeds. M. de Fourcroy had ascertained that some of the calculi found in animals were capable of being dissolved by a weak solution of vinegar, and he had conceived some hopes that the observation might be applied with advantage to similar diseases in the human subject. His investigations respecting calculi, however, notwithstanding their importance, were in a great measure anticipated by the acute penetration of our celebrated countryman Dr Wollaston, though his paper is not mentioned by M. de Fourcroy. 105. *Notice of the Chimie Optomathique*, xxxi. 106. *Account of a Memoir of Fabroni on Fermentation and on Ether*, ib. 107. *Chemical Novelties*, xxxii. 108. *Report on Paul's Artificial Waters*, xxxiii. 109. *On Dabit's Ether*, xxxiv. 110. *On the Identity of the Three Empyreumatic Acids with the Acetic*, xxxv.; suggesting that they might be substituted for it in some economical processes. 111. *Galvanic Experiments*, xxxix.; by Fourcroy, Vauquelin, and Thénard. 112. *Note in answer to Proust*, xlii. 113. *Remarks on a Memoir of the Dutch Chemists on the Carbonic Oxide*, xliii. 114. *On a New Phosphate found in the Bones*, xlvii.; that of magnesia, not before observed. 115. *Extract of a Memoir on Platina*, xlviii. 116. 117. *Two Memoirs on Crude Platina, and on a Metal found with it*, xlix. l. These researches were less successful than those of Mr Tennant, Dr Wollaston, and Mr Descorils, which were completed about the same period. 118. *Extract from Izarn's Manual of Galvanism*, l. 119. *On the Alumina of Saxony*, lii. 120. *On a Fluid found in the Caoutchouc of the Castilloya Elastica*, lv. 121. *On a Detonating Substance formed by the Action of the Nitric Acid on Indigo and Animal Matters*, lv.; the investigations relating to indigo have since been carried further by Mr Hatchett. 122. *On the Products of Animal Substances treated with the Nitric Acid*, lvi.; yielding more azote as they are more highly animalized. 123. *On the Guano*, (39), lvi. 124. *Experiments on Ivory, Recent and Fossil, and on the Enamel of the Teeth, in search of the Fluoric Acid*, lvii.; these experiments were not completely successful, though Morichini had detected the fluoric acid in the teeth before that time, and Berzelius has found it still more recently.

M. de Fourcroy was for some years the editor of the *Journal des Pharmaciens;* he first suggested the idea of the publication of the *Annales du Muséum d'Histoire Naturelle*, and contributed several valuable papers to it, as well as to the *Journal de l'Ecole Polytechnique*, and to the *Magazin Encyclopédique.* He was also the author of some very voluminous articles in the chemical part of the *Encyclopédie Methodique;* but the fabric of his celebrity is principally founded on the works which have already been enumerated, and which are better known to the public.

(Palissot de Beauvois, *Eloge Historique*, Par. 1810; Cuvier, *Eloge*, M. Inst. A. Math. 1810, and in Biographie Universelle, xv. 8. Par. 1816; Thomson's *Annals*, i. May

1818, p. 321; Aikin's *General Biography*, vol. x. 4to, Lond. 1815.) (L. L.)

FOURMONT, Stephen, professor of the Arabic and Chinese languages, and one of the most learned men of his time, was born at Herbelai, near Saint Denis, about four leagues from Paris, in 1683. He studied in Mazarin College, and afterwards in the Seminary of Thirty-three. He was at length appointed professor of Arabic in the Royal College, and admitted a member of the Academy of Inscriptions. In 1738 he was chosen a member of the Royal Society of London, and in 1741 a member of that of Berlin. He was often consulted by the Duke of Orleans, first prince of the blood, who had a particular esteem for him, and made him one of his secretaries. He was the author of many learned works, the most important of which are, 1. *Racines de la Langue Latine mises en vers François*, Paris, 1706, in 12mo; 2. *Réflexions Critiques sur les Histoires des Anciens Peuples*, Paris, 1735, in 2 vols. 4to; 3. *Meditationes Sinicæ*, 1737, in folio; 4. *Grammatica Sinica* (Chinese Grammar), 1742; and, 5. Several Dissertations printed in the *Mémoires de l'Acad. des Inscriptions.* Fourmont died at Paris on the 18th December 1745, at the age of sixty-two. He must not be confounded with *Michel Fourmont*, his youngest brother, who was professor of the Syriac language in the Royal College, and a member of the Academy of Inscriptions, and who died in 1746.

FOURNESS, in Loynsdale, Lancashire, is a tract between the Kent, the Leven, and the Dudden sands, which runs north parallel with the west sides of Cumberland and Westmoreland, and on the south runs out into the sea as a promontory. Here, as Mr Camden expresses it, "the sea, as if enraged at it, lashes it more furiously, and in high tides has even devoured the shore, and made three large bays; viz. Kentsand, into which the river Ken empties itself; Levensand and Duddensand, between which the land projects in such a manner that it has its name hence; Foreness and Foreland, signifying the same with us as *promontorium anterius* in Latin." Bishop Gibson, however, derives the name of *Fourness*, or *Furness*, from the numerous furnaces that were there anciently, the rents and services of which, called *Bloomsmithy rents*, are still paid. This whole tract, except on the coast, rises in high hills and vast piles of rocks called *Fourness-Fells*, amongst which the Britons found a secure retreat, trusting to these natural fortresses, though nothing was inaccessible to the victorious Saxons; for we find the Britons settled here 228 years after the arrival of the Saxons; because at that time Egfrid king of Northumberland gave St Cuthbert the land called *Carthmell*, and all the Britons in it, as is related in his life. In these mountainous parts are found quarries of a fine durable blue slate, which is made use of to cover buildings in this and many other parts of the kingdom.

FOU-TCHANG, a city of China, in the province of Pe-tche-li, situated on the banks of the grand canal. It is an ancient city, but the gates at the extremities are in a state of decay. It has a bridge of great antiquity, consisting of four large arches and three smaller ones, secured by parapets; the whole of which is crumbling down.

FOU-TCHEOU, a city of China, of the first rank, which is celebrated for a magnificent bridge built of stone, with 100 arches, and a double balustrade along the whole length. The city is governed by a viceroy, and has nine others under its jurisdiction. It is the residence of many literati, and has a good harbour. Fou-tcheou is 870 miles south of Pekin. Long. 119. 4. E. Lat. 20. 4. N. This is also the name of a city of the third rank, which was almost ruined by an invasion of the Tartars. It is 735 miles south of Pekin.

FOWEY, a market-town and seaport of the county of Cornwall, in the hundred of Powder, 239 miles from London. The harbour, deemed the best on that part of the coast, is formed by the river Fowey, which there empties itself into the channel. There is space and depth of water for 1000 vessels. It has, however, but little trade, except that which in the few months of summer consists in the catching of pilchards, which, though a casual, is sometimes a source of great profit. The mouth of the river is defended by several forts of various dates. It is governed by a mayor, recorder, and eight aldermen, and returns two members to the House of Commons, chosen by the inhabitant householders. The population amounted in 1801 to 1155, in 1811 to 1457, in 1821 to 1455, and in 1831 to 1767.

FOWL, among zoologists, denotes the larger sorts of birds, whether domestic or wild; such as geese, pheasants, partridges, turkeys, ducks, and the like.

FOWLING, the art of catching birds by means of birdlime, decoys, and other devices, or the killing of them by the gun.

Fowling is also used for the pursuing and taking birds with hawks, more properly called falconry or hawking.

FOX, in *Zoology*. See Mammalia.

Fox, *John*, the martyrologist, was born at Boston in Lincolnshire, in the year 1517. At the age of sixteen he was entered a student of Brazen-Nose College in Oxford; and in 1543 he took his degree of master of arts, and was chosen fellow of Magdalen College. He discovered an early genius for poetry, and, conformably to the taste of his age, wrote several Latin comedies upon subjects taken from Scripture. Of these, one still remains, entitled *De Christo Triumphante*, printed at London in 1551, and at Bâle in 1556, 8vo, and reprinted in 1672. But having forsaken the muses, he applied himself with great assiduity to the study of theology, including church history; and having manifested an inclination, which he took no pains to conceal, for the doctrines of the reformation, he was, in the year 1545, expelled from his college as a heretic, happy, it is said, to have fared no worse. He had lost his father early in life, and, as his mother had married again, his stepfather availed himself of this occurrence to retain the whole of his patrimony, knowing that Fox would not venture to sue him for restitution. This rascality on the part of his mother's husband reduced him to the greatest distress; but he soon afterwards found an asylum in the house of Sir Thomas Lucy, Warwickshire, who employed him as tutor to his children. When this engagement expired, Fox, who had in the meanwhile married the daughter of a citizen of Coventry, proceeded to London; but finding no immediate means of subsistence, he was again reduced to absolute want. Relief, however, at length came, and in a manner which is described as almost miraculous. As he was one day sitting in St Paul's church, emaciated with hunger, a stranger accosted him familiarly, and, bidding him be of good cheer, put a sum of money into his hand; telling him, at the same time, that new hopes were at hand. And, in fact, he was, three days thereafter, received into the family of the Duchess of Richmond, as tutor to the Earl of Surrey's children, who, upon their father being sent to the Tower, were committed to her care. In this family he lived at Ryegate in Surrey, during the latter part of the reign of Henry VIII., the entire reign of Edward VI., and part of that of Queen Mary; but he could never discover the generous person who had at once relieved his distress and predicted his good fortune. At length, however, being persecuted by his implacable enemy Bishop Gardiner, he was obliged to seek refuge abroad; and he selected as the place of his retreat Basil in Switzerland, where he subsisted by correcting for the press. But on the death of Queen Mary he returned to England, where he was graciously received by his former pupil the Duke of Norfolk, who retained him in his family as long as he lived, and bequeathed him a pension at his death, which took place in 1563. Mr Secretary Cecil also bestowed on him a rectory near Salisbury; and, in point of fact, he might have obtained considerable church preferment, had it not been for his unwillingness to subscribe to the canons. He died in the year 1587, in the seventieth year of his age, and was buried in the chancel of St Giles's, Cripplegate. Fox was a man of great industry, and considerable learning; a zealous, but not a violent reformer; a nonconformist, but not an enemy to the Church of England. The most celebrated of his works is that which is entitled *Acts and Monuments of the Church*, and commonly called *Martyrology*, containing a history of the troubles in the church of Rome since the tenth century, particularly in England and Scotland. It was published at London, 1563, in folio, but afterwards augmented, and printed for the fourth time in 1583, two vols. folio, and in 1632, three vols. folio. He relates in detail the history of the martyrs of the Protestant religion, but embellishes his narrative with so many marvellous circumstances, that his enemies, it must be confessed, had some reason in applying to it the name of Legend. The Catholics, in particular, reproached him with passion and with grossness; and, what was far more serious, accused him of having often altered the truth in order to swell the number of martyrs to his creed. Nor can it be denied that, in the first edition, he had enrolled amongst the number of those who had sealed their testimony with their blood, persons still living, and who remonstrated against the honour intended for them. But notwithstanding all these and many other objections, some of which are undoubtedly well founded, the *Martyrology* met with prodigious success in England, where, amidst all the changes which have taken place in taste and opinion, it still maintains its ground. The other writings of Fox, which were very numerous, consist of works on theology, and particularly controversy; and some of his letters which have been preserved reflect honour on his character as a man of sense and humanity.

Fox, *George*, the founder of the sect of Quakers, was born at Drayton, Leicestershire, in the year 1624. His father, a zealous Presbyterian, was a weaver. Young Fox, from his earliest years, showed uncommon gravity, and participated in none of the diversions natural to his age; he courted solitude, and when he spoke it was in a melancholy tone. His parents were unable to give him any education beyond reading and writing, but they early inspired him with sentiments of religion and virtue. Fox was at first placed with a wool-merchant, and sent to tend sheep in the woods; a circumstance which seems to have confirmed his inclination for a solitary and contemplative life. He was then put as an apprentice to a shoemaker at Nottingham; and from the accounts of the times we learn, that as he wrought at his trade, he used to meditate much on the Scriptures, which, with his solitary course of life, improving his natural melancholy, induced him at length to fancy himself inspired; and in consequence he set up as a preacher. He proposed but few articles of faith, insisting chiefly on moral virtue, mutual charity, the love of God, and a deep attention to the inward motions and secret operations of the Spirit; he required a plain, simple worship, and a religion without ceremonies, making it a principal point to wait in profound silence for the directions of the Holy Spirit. Fox met with much rough treatment on account of his zeal, was often imprisoned, and several times in danger of being put to death. But, in spite of all discouragements, his sect, which received the name of *Quakers*, prevailed, and many considerable men were led to join them; amongst whom were Barclay and Penn. Fox died on the 16th of January 1690. He was comparatively an uneducated man, as we have already seen; but he possessed in an eminent degree the talent of persuasion, since, although born in an inferior grade of society, and devoid of any but the simplest instruction, he succeeded in recommending his doctrine to men of a superior rank in society. It was undoubtedly owing to this circumstance that the society of Quakers, or, as they call themselves, Friends, was enabled to outlast so many other sects, founded by enthusiasts, which have generally disappeared immediately after the death of their authors; whereas Quakerism acquired every day new force, and the laws which at first persecuted, ended by tolerating, and even protecting it. Fox, however, only laid the foundation; it was reserved for Barclay and Penn to raise the superstructure. The writings of Fox have been collected in three volumes folio; the first containing his Journal, which is eminently curious; the second, his Correspondence; and the third, all that he has written on his Doctrine. Some persons have indeed pretended that he is not really the author of these different productions; but his followers, on the other hand, maintain that whatever is most admirable in this collection really proceeded from the pen of their patriarch.

FOX, Charles James, a celebrated statesman and orator, was third son of the Right Honourable Henry Fox, afterwards Lord Holland, and of Lady Georgina Caroline Fox, eldest daughter of Charles, second Duke of Richmond. He was born on the 24th January 1749.

Mr Fox received the first rudiments of his education in a private school of some celebrity, kept by a Mr Pampelune at Wandsworth. In 1758 he was sent to Eton, where he gave early promise of future eminence. In the beginning of summer 1763 the mistaken indulgence of his father carried him first to Paris, and then to Spa. After wasting idly three months abroad, he was sent home to England, and at his own desire he went back to Eton. He had left school a boy; he returned to it with all the follies and fopperies of a young man. At Spa he had been initiated in play; and his father, whose fondness for him was excessive, had encouraged him in a propensity which was the source of much future unhappiness to both.

In the autumn of 1764 he was removed from Eton and sent to Oxford, where he was placed at Hertford College, under the tuition of Dr Newcome, afterwards primate of Ireland. At Oxford as well as at Eton he distinguished himself not less by his powers of application than by the quickness and superiority of his parts. The following letter, which he preserved with care, and used to show with triumph when reproached for idleness, is a curious document of his diligence in study while he was at college. "You judge rightly," says Dr Newcome in a letter to his pupil, "in thinking that I should be much surprised by the information which you were so obliging as to give me. But, on reflection, I think you have done well to change the scene in such a manner, and I feel myself inclined to envy you the power of doing it. Application like yours requires some intermission; and you are the only person with whom I have ever had connection to whom I could say this. I expect that you will return with much keenness for Greek, and for lines and angles. As to trigonometry, it is matter of entire indifference to the other geometricians of the college (who will probably continue some time here), whether they proceed to other branches of mathematics immediately, or wait a term or two longer. You need not, therefore, interrupt your amusements with severe studies; for it is wholly unnecessary to take a step onwards without you, and therefore we shall stop till we have the pleasure of your company. All your acquaintances here whom I know are well, but not much happier for your absence." This letter was probably written in spring 1765, when Mr Fox made a second excursion to Paris with his mother.

In autumn 1766 he quitted Oxford, and accompanied his father and mother to the south of Europe, where Lord Holland had been advised to pass the winter on account of his health. He remained with them at Naples during the winter, and not finding a good Italian master there, taught himself that language. In the following spring he attended them as far as Turin in their way to England, and then went to Genoa to meet Lord Fitzwilliam, with whom and Mr Uvedale Price he spent the summer in Italy, chiefly in Tuscany. In the beginning of winter he rejoined his father and mother at Paris, and accompanied them to Nice, where he passed with them the winter of 1767–68. It was during this long residence in Italy that he contracted his strong partiality for Italian literature. In a letter to Mr Fitzpatrick, written from Florence in September 1767, he conjures him to learn Italian as fast as he can, if it were only to read Ariosto. "There is more good poetry in Italian than in all other languages I understand put together." He appears to have indulged freely at this period in all the pleasures natural to his time of life, but never to have intermitted entirely his application to study. *Je travaille toujours le matin*, he says, in another letter written from Nice. Acting plays was also at this time one of his favourite passions, though he confesses that the last time he acted he fell far short of his own expectations; "but then," he adds, "my expectations, it must be confessed, were very high." In the course of this journey he made a visit to Voltaire at Fernay, in company with Mr Price.

He did not return to England till August 1768; and having been elected one of the burgesses for Midhurst in his absence, he took his seat in the ensuing session, and made his first speech in the House of Commons on the 15th of April 1769, in support of the decision in favour of Colonel Luttrel, on the famous Middlesex election. He spoke, says Horace Walpole, with insolence, but with infinite superiority of parts.

Lord Holland, father to Mr Fox, had begun his political career as an adherent of Sir Robert Walpole, and continued ever after one of the steadiest friends and warmest admirers of that great statesman. The treachery of the Pelhams to his patron excited an early prejudice in his mind against all the members of that family; and the falseness, folly, and fickleness of the Duke of Newcastle added contempt and distrust to his dislike. After a long rivalship with Mr Pitt, he was finally driven from the cabinet by a coalition of the Pitt and Newcastle parties, and reduced to the subordinate though lucrative employment of paymaster of the forces. In this situation he was found by Lord Bute at the conclusion of the war, and recommended to the king as the only person in the House of Commons who had courage and ability to defend the peace against Mr Pitt and the Newcastle party. It was with great difficulty he was prevailed on by his majesty to undertake this office, but when engaged in it, he performed it most successfully. For his services on this occasion he was rewarded with a peerage; but the part he had taken estranged him for ever from his old friends the Dukes of Cumberland and Devonshire, and other leaders of the Whig party. It was at this period that his son Charles received his first political impressions; and there is still extant a copy of French verses written by him in 1764, in praise of Lord Bute, and full of invective against Mr Pitt. When brought into parliament, he was, therefore, in the first instance, connected with the Duke of Grafton's administration, which, though originally formed under the auspices of Lord Chatham, had been gradually sinking into a mere court party.

Mr Fox was not of age when returned to parliament, and probably for that reason, after his first speech, he took little part in public debate till January 1770. During this interval he made another excursion to the Continent, where he is chiefly taken notice of for his losses at play. He had, as already mentioned, acquired a passion for play as early as his first journey to Spa; and for many years afterwards, when not engaged in active political business, play and Newmarket were his chief avocations. His losses were such as early to embarrass, and finally to ruin, his private fortune; but so great a hold had these pursuits taken of his mind, that, till the payment of his debts in 1794, he could never prevail on himself to renounce them entirely. From that moment he gave them up for ever.

In February 1770 he was rewarded for his support of government with the place of junior lord of the admiralty, which he retained for two years, and resigned on the 20th of February 1772, partly in consequence of some slight offence he had received from Lord North, and partly because he had resolved to oppose the royal marriage bill, "which, *in place*," he says, "I should be ashamed of doing;" but he had no thoughts, he adds, "of going into opposition." He had an immediate and satisfactory explanation with Lord North; but, to punish him for his speech against the royal marriage act, which was a measure entirely the king's own, he was suffered to remain a considerable time out of office. At length, in January 1773, he was made one of the lords of the treasury, a situation he continued to fill till his memorable quarrel with Lord North in the following year.

Some gross and scandalous reflections upon the speaker of the House of Commons, written by the celebrated Horne Tooke, having appeared in the Public Advertiser, Mr Woodfall, the printer of that newspaper, was called to the bar of the house, and having there confessed himself publisher of the libel, he was declared guilty of a breach of privilege; on which Mr Herbert moved that he should be taken into the custody of the serjeant-at-arms. The house, unwilling to engage in a fresh contest with the press and the city, were disposed to acquiesce in this motion; but Mr Fox, thinking the punishment inadequate to the offence, without consulting Lord North, moved, as an amendment, that Mr Woodfall should be committed to Newgate. Lord North found himself compelled by this motion to resist Mr Herbert's proposition; but though he substituted the Gatehouse for Newgate, as a less objectionable place of confinement, he was left in a minority on the division, the original motion being carried by a great majority. Incensed at this disgrace, and determined to punish his youthful colleague for his temerity, he had a new commission of the treasury made out a few days afterwards, in which the name of Mr Fox was omitted. This happened in February 1774.

Long before his breach with Lord North, Mr Fox had formed an intimate acquaintance with Mr Burke, one of the leading members of the Whig or Rockingham party in the House of Commons; and to the friendship he contracted with that gentleman may, in a great measure, be attributed the decided change in his political character and opinions, which commenced at this time. He had been brought up by his father in the maxims and principles of Sir Robert Walpole; and from this education he derived the love of peace, the good-humoured spirit of conciliation, and ardent attachment to civil and religious liberty, which were afterwards the most conspicuous features of his public character, and are certainly the chief merits of the Walpole school. But the tone and character of Sir Robert Walpole's policy, though suitable, and perhaps necessary, for the times in which he lived, was no longer adapted to the state of the country. When the Jacobites renounced their idol without changing their creed, and transferred to the house of Brunswick the same allegiance which they had borne to the Stuarts, the weapons which Sir Robert had employed to preserve the constitution became, in the hands of its enemies, instruments of its destruction. Mr Burke was the first to perceive, or at least the first to explain, the change that had taken place in our internal government, and the first to point out a plan of systematic opposition in parliament, as the only means of preventing, or at least of retarding, what Mr Hume has called the *euthanasia* of English liberty. In Mr Fox he found a pupil ready to receive his lessons, and prepared by character and turn of mind to act upon them with fortitude and perseverance. From Mr Burke's example and instructions Mr Fox caught more elevated notions of public principle than had animated the successors of Sir Robert Walpole; and from the writings and conversation of the same great man he learned the necessity of party connections in a mixed government like ours, to counteract the influence of government, and preserve a due balance of power between the crown and the people. The American war roused all the energies of his mind. The discussions to which it gave rise involved all the first principles of free government. The vicissitudes of the contest tried the firmness of its opponents. Its duration exercised their perseverance. Its magnitude and the dangers of the country called forth their powers. The progress of Mr Fox was steady and uninterrupted. So early as the beginning of 1775, we are told by Gibbon that "he discovered powers for regular debate, which neither his friends hoped nor his enemies dreaded."

But, notwithstanding the brilliancy of his talents and the reputation he acquired in the House of Commons, the levity and want of decorum of his private life, the dissipation in which he indulged, and the embarrassments in which he was involved, prevented him, for some years, from obtaining the weight and consideration with opposition, due to his extraordinary abilities and exertions. So late as the beginning of 1778 he was under no engagements with any set of men; but, though not absolutely engaged in party connections with the Whigs, he had determined on no account to abandon their principles; and from a cool consideration of his own character, and a just conception of the prevailing sentiments of the country, he had already fully made up his mind to the fate that ultimately awaited him. "People flatter me," he says in a letter to Mr Fitzpatrick, written in 1778, "that I continue to gain rather than to lose character as an orator; and I am so convinced this is all I ever shall gain (unless I chuse to be one of the meanest of men), that I never think of any other object of ambition. I am certainly ambitious by nature, but I have, or think I have, totally subdued that passion. I have still as much vanity as ever, which is a happier passion by far, because great reputation, I think, I may acquire and keep; great situations I never can acquire, nor, if acquired, keep, without making sacrifices that I will never make. If I am wrong, and more sanguine people right, *tant mieux*, and I shall be as happy as they can be; but if I am right, I am sure I shall be happier for having made up my mind to my situation." He expresses great joy at the prospect of Fitzpatrick's return, who he knew would be of his opinion in certain emergencies that might arise. "I shall be told by prudent friends that I am under no sort of engagements to any set of men. I certainly am not; but there are many cases where there is no engagement, and yet it is dishonourable not to act as if there was one. But even suppose it were quite honourable, is it possible to be happy in acting with people of whom one has the worst opinion, and being on a cold footing (which must be the case) with all those whom one loves best, and with whom one passes one's life?" With these sentiments it is not to be wondered at that he rejected overtures made to him by Lord Weymouth, in summer 1778, to join administration; nor, with his powerful talents and unremitted exertions, the inflexible steadiness of his public conduct, and the unexampled force and vehemence of his eloquence, that he gradually acquired the perfect confidence of the Whigs, and came at length to be considered as the leading member of the Rockingham party in the House of Commons. It ought to be recorded to the credit of Mr Burke, that he witnessed with pleasure, unmixed with envy, the progress and elevation of his pupil, and cheerfully resigned to him the station he had so long himself occupied in the party.

The day of triumph at length arrived. A resolution against the further prosecution of the American war was carried in the House of Common. Ministers still lingered in office, but the fears of a direct vote of censure compelled them to resign. The king, whose pertinacity in support of his favourite principles of government had been the chief if not the sole cause of the apparent reluctance of his ministers to retire from office, was compelled at length to yield to the wishes of his Commons; but in the very act of forming a new administration, he contrived to sow the seeds of disunion in its bosom. The opposition to the American war had been composed of two parties, united in their disapprobation of that contest, but disagreeing on many other points of external as well as of internal policy; both calling themselves Whigs, but Whigs of different schools; the one consisting of the old Whig connection, formed and educated in the principles of Mr Burke; the other composed of the friends and followers of Lord Chatham. At the head of the first was the Marquis of Rockingham, whilst the leader of the second was the Earl of Shelburne. His majesty began by sounding Lord Rockingham, through the chancellor. The demands of Lord Rockingham were, to have full power to recognise the independence of America, and authority to bring forward, as ministerial measures in parliament, bills for reducing the influence of the crown, by abolishing offices, excluding contractors from the House of Commons, and depriving revenue officers of their votes at elections; and, with respect to reform in the representation, or limitation of the duration of parliament, he declined to lay himself under restrictions. After taking time to consider this answer, his majesty sent for Lord Shelburne, and had a conference with him at Buckingham house. Two days afterwards he sent for him again, and offered him the treasury, which his Lordship declined, saying that no administration suited to the present emergency could be formed unless Lord Rockingham was at the head of it; on which the king desired him to go to Lord Rockingham with an offer of the treasury, and to add, that he had full powers from his majesty to treat both with respect to men and measures, with one reservation only, that he should himself be one of the secretaries of state. The first impulse of Lord Rockingham was to decline this offer, upon the ground, that if it was the king's intention to place him at the head of the treasury, his majesty could have no fit objections to conversing with him on the arrangement of the administration; but his friends persuaded him to overlook that objection, lest his refusal should be ascribed to pique or jealousy, at a moment when the public was extremely impatient for the formation of a government. Many fatal consequences ensued from the negotiation taking this course and passing through the hands of Lord Shelburne. No direct communication took place between the king and the Rockingham party, who were to compose the majority of the cabinet, with respect to the measures to be pursued, till after the administration had been formed. Lord Thurlow, a decided partisan of the old system, and an enemy to every species of reform, was retained as lord chancellor; Mr Dunning having been prevailed upon by his friend Lord Shelburne to waive his pretensions to that office. When this arrangement was communicated to Mr Fox, he told Lord Shelburne plainly, "that he perceived the administration was to consist of two parts, one belonging to the king, the other to the public." But the worst effect of all was the impression left on the mind of Lord Shelburne, that he alone possessed the confidence of his sovereign, to the exclusion of his colleagues. This persuasion bred distractions in the cabinet, which soon became a theatre of dissension and open division; and these divisions, whispered about, weakened the government whilst it lasted, and contributed materially to its fall.

Of this short-lived administration, the principal measures were the pacification of Ireland and the bills for economical and parliamentary reform, which, though short of the public expectation, are still the most important acquisitions of that description obtained since the accession of the house of Hanover. The death of Lord Rockingham dissolved the ministry over which he presided. The treasury was immediately offered to Lord Shelburne, on pretence that, having refused it before, it naturally devolved on him on Lord Rockingham's death. His acceptance of it destroyed the former balance of parties in the cabinet, and overset entirely the balance of power in the government. Accordingly Mr Fox and Lord John Cavendish immediately resigned, and, after some interval, they were followed by Lord Keppel. The Duke of Richmond and General Conway remained in office; the latter from simplicity, the former from dissatisfaction at seeing the Duke of Portland preferred to himself as leader of the Whig party. The other members of the cabinet were friends of Lord Shelburne.

Mr Fox has been severely blamed for his precipitancy on this occasion; and, though his resignation was a measure that could not long have been deferred, the time at which it took place makes it perhaps liable to that imputation. It followed so immediately the appointment of Lord Shelburne to the treasury, as to have the appearance of being the result of disappointed personal ambition, rather than of any difference on public grounds. It reduced his friends who were in office to the alternative of immediately following his example, or of passing for adherents of Lord Shelburne; and, as the whole of his motives could not at that time be explained in public, it gave an opportunity to the Duke of Richmond and others to keep their places without forfeiting their characters. It took place at the close of a session of parliament, and left Lord Shelburne and the court for six months in undisturbed possession of the government. It was a cruel disappointment to the public, which had expected a firm and united administration on the principles of those who had opposed the American war and the system that gave rise to it. But to those who judged rightly, the elevation of Lord Shelburne to the treasury was the utter extinction of these hopes. The Rockingham party had found in Lord Shelburne an active and spirited ally in opposition; but they had never been confidentially united with him; and though ready to co-operate with him in a subordinate office, they were not prepared to act under him as premier. It was not the impatience and dissatisfaction of Mr Fox alone that broke up the administration. As soon as the appointment of Lord Shelburne to the treasury was known in Dublin, the Duke of Portland determined to resign his office of lord-lieutenant of Ireland. Lord John Cavendish could with difficulty be prevailed upon to postpone his resignation for a few days. Mr Burke urged strongly to Mr Fox the impossibility of his remaining long in office as a clerk under Lord Shelburne; and it must be owned that, in the subsequent treatment of his colleagues, that nobleman fully justified the apprehensions then entertained of his future conduct. Elated with the fancied possession of court favour, he from that time forward treated the other ministers as mere ciphers; made additions to his cabinet without consulting or even apprising them of his intentions; and is even said to have settled and concluded the terms of his peace with France, without the advice or participation of his secretaries of state.

There were, besides, before the death of Lord Rockingham, differences of such importance in the cabinet as must have led to a dissolution of the administration. It was the policy of Mr Fox to detach Holland and America from their unnatural connection with France; and the great object of his foreign politics was, to form a continental alliance as a balance against the house of Bourbon. The system of Lord Shelburne was to conciliate France, to cultivate a confidential understanding with her government, and to treat her allies as so many inferior and dependent powers. Mr Fox had recommended and carried in the cabinet (23d May 1782) a resolution to instruct Mr Grenville, his majesty's plenipotentiary at Paris, to propose the independence of America in the first instance, instead of making it a condition of a general treaty; and this offer, to which his majesty's consent had been obtained, was actually communicated by Mr Grenville to Dr Franklin. Lord Shelburne, though obliged to acquiesce in the determination of the cabinet, endeavoured afterwards to represent the offer as only conditional, to be recalled if not accepted as the price of peace; and this explanation having been adopted by a majority of the cabinet after the illness of Lord Rockingham, Mr Fox declared his determination to resign. The discovery of a mysterious negotiation at Paris contributed to strengthen this resolution. It was a great object with Mr Fox, in pursuance of his system of policy, to open a free and unreserved communication with Dr Franklin. Through Mr Grenville he had hoped to accomplish this design, and he had nearly succeeded in his purpose, when he had discovered, to his infinite surprise and indignation, that Lord Shelburne had been carrying on a clandestine intercourse with Franklin through Mr Oswald, and had received from him and made to him important communications, which had not been imparted to his colleagues. This discovery, which was made before Lord Rockingham's death, destroyed all confidence in Lord Shelburne among the friends of that nobleman, though, from the delicate nature of the transaction, it was impossible at the time to make it the subject of public animadversion, or even allusion.

The resignation of Mr Fox and his friends compelled Lord Shelburne to strengthen his government from every quarter where support could be obtained. Mr Pitt, who had declined accepting a subordinate office in the Rockingham administration, became his chancellor of the exchequer. Rigby, Dundas, and Jenkinson, old supporters of the American war, attached themselves to his train. A negotiation was opened with the remaining partisans of Lord North, which only failed of success in consequence of Mr Pitt, with more judgment than feeling, making personal objections to Lord North himself, which wounded the pride, and excited the indignation, of his friends and family. When parliament met after the signing of the preliminaries of peace, there were three parties, nearly of equal strength, in the House of Commons; that of the minister, reinforced by the court, and several of the most objectionable members of Lord North's administration; the Rockingham party, who had gone into opposition with Mr Fox; and, lastly, Lord North and his friends. That three separate parties, so equally balanced, should continue to act in the House of Commons without some coalition, was not to be expected. A re-union of the

Whigs would have been most acceptable to the public; but recent differences, mutual recriminations, and distrust of Lord Shelburne, rendered such a coalition impracticable. The personal objections, so harshly and acrimoniously stated, against Lord North, had exasperated his friends against the ministry. Nothing, therefore, remained but a junction of the two parties in opposition; and this coalition, which time would naturally and imperceptibly have brought about, was hastened and matured by the coincidence of their opinions against the peace. The first step was to concert an amendment to the address of thanks on the preliminary articles signed at Versailles; and this amendment was carried in the Commons by a small majority, but not without great indignation being expressed in the house, and a violent outcry raised out of doors, at the apparent junction of the two parties. No coalition had yet taken place. Lord North was still at liberty to have formed an administration without Mr Fox; and it was the opinion of one of the most judicious friends of the latter, that to undertake the government with Lord North, "was to risk their credit with the public on very unsafe grounds." On the part of the Whigs there seems to have been a momentary hesitation whether to proceed farther or to step back. "Unless a real good government is the consequence of this junction," says one of the most sagacious of the party, "nothing can justify it to the public." "There never was a case of more difficulties and dangers to the real friends of whiggism and good principles." The die was at length cast; and in an evil hour, if we are to judge, not from principles, but from results, the coalition was effected. The united strength of the two parties procured a vote of censure on the peace. Lord Shelburne, who still flattered himself with the possession of court favour, is said to have proposed an immediate dissolution of the parliament. But he had served his turn, and was no longer wanted. His majesty judged rightly, that the time was not yet come for so bold a measure, and allowed his minister to resign.

A long interval ensued before the coalition administration was formed. Repeated attempts were made to detach Lord North from Mr Fox; and when these had failed, it was stated as an indispensable preliminary to any ministerial arrangement, that Lord Thurlow should be continued as lord high chancellor. But the fatal effects of a secret enemy in the cabinet had been too severely and too recently felt to concede a point of so much importance. A complete change of administration was insisted upon, and was granted at last, but with the worst possible grace, and with every symptom of ill humour and dissatisfaction. It was not merely the triumph of the coalition that filled the royal bosom with such indignation. His majesty considered the Rockingham party as enemies to his just prerogative. Nor could he forgive them for their zeal against the American war, and inflexibility, when they came into office, in insisting on the unconditional acknowledgment of American independence. "The extraordinary and never to be forgotten vote of February 1782, and the hurry for negotiation that after ensued," had, in his opinion, lowered the spirit of the country, and given confidence to its enemies; and in his own mind had produced such indifference on political subjects, that he felt no anxiety for the arrival of the definitive treaty, or concern for the delays that retarded its conclusion. When it was suggested to him that a wish on his part to receive a minister from America would be favourably received in that country, and might tend to preserve peace and restore harmony in future, he is said to have replied with bitterness, that to receive a minister from America, he could never say would be agreeable to him; and that he should ever have a bad opinion of any Englishman who could accept being an accredited agent to that revolted state. With such feelings rankling in his mind, is it to be wondered at that his majesty was hostile to an administration, the majority of which had zealously concurred in the grant of independence to America?

The coalition ministry was hardly settled, when a misunderstanding arose about the establishment of the Prince of Wales; and so skilfully had the affair been managed on the part of the king, that if his royal highness had not submitted entirely to his father's pleasure, the administration must have been overturned almost as soon as formed. But though no change was attempted before the meeting of parliament, his majesty contrived on every occasion to show ill humour to his ministers, and no one in a situation to observe could doubt for a moment that he only waited for a favourable opportunity to turn them out. The India bill afforded such opportunity. That measure was represented as an invasion of chartered rights, as the establishment of a ministerial oligarchy, independent both of prince and people. The nation, disgusted and offended at the coalition, listened with credulity and favour to these accusations. The king, who had carefully disguised his sentiments to the last moment, procured the rejection of the bill in the Lords, through the agency of Lord Temple, and instantly dismissed his ministers.

The coalition ministry was at an end, but its leaders still possessed the confidence of the House of Commons. The cry of secret influence was raised, and more violent addresses carried to the throne than had ever been presented to any prince of the house of Brunswick. Lord Temple, who had accepted the seals, grew frightened at the storm he had raised, and gave in his resignation. Even Mr Pitt became alarmed in the progress of the contest; and the firmness of the Duke of Richmond alone prevented him from following the example of his kinsman. But, as the struggle proceeded, the voice of the people was every day more unequivocally declared in support of the new administration. Courtiers and reformers, churchmen and dissenters, squires and nabobs, joined in execrating the coalition and applauding the minister, in professions of attachment to the king, and declarations of hostility to the Commons. After the attempt of the country gentlemen to make a new coalition of parties had failed, the majorities of opposition began to diminish; and when some necessary votes had been obtained, this refractory House of Commons was punished by a premature dissolution, for its want of subserviency to the crown.

Our limits will not permit us to follow with the same minuteness the political life of Mr Fox in the subsequent parts of his public career. From 1784 to 1792 he was leader of a powerful party in the House of Commons, in opposition to Mr Pitt. His most remarkable exertions during that period were against the Westminster scrutiny, on the regency, against the abatement of impeachments by a dissolution of parliament, on the libel bill, and on the Russian armament. He never published nor corrected any of his speeches, except the one on moving a new writ for the borough of Tavistock; and of those which appeared in the newspapers, and have since been collected, his speech on the scrutiny is the only one so well reported as to give the reader an adequate notion of his style of speaking. It failed at the moment in procuring justice for the Westminster electors; but the impression it made on the house was such, that in the following year an end was put to that odious and vexatious piece of chicanery, worthy of the pettyfogging genius of its inventor, but disgraceful to the minister who gave it his countenance and support. We have not room to discuss at length the regency question. The case was new and unprovided for.

There was no direct precedent, nor legal authority in the kingdom to make one. Constitutional analogy pointed out the heir-apparent as the fittest person to exercise the royal authority during the indisposition of the king; and the same analogy indicated the great council of the realm as the body most competent to declare the incapacity and apply the proper remedy. Strict or legal right there was none on either side. The prince had no legal right to the regency; nor till they chose to declare it themselves, had the two houses of parliament any legal right to elect a regent, or to fetter him, previous to his election, with restrictions. The contrivance to create, first a phantom, and then a regent, was a clumsy piece of machinery, nearly allied to treason. The claim of right advanced for the prince was a flimsy speculation of Lord Loughborough, adopted on his authority, without due examination, by Mr Fox, who returned in haste from Italy, while the discussions on the regency were pending. As explained afterwards, the doctrine, if not true, was at least harmless. But the opportunity was skilfully laid hold of by the minister, for the purpose of making his rival unpopular, and of gaining time for the king's recovery, which Addington, who had great experience in such maladies, assured him, from the beginning, would certainly take place. In his argument against the abatement of impeachment by a dissolution of parliament, Mr Fox had the support of Mr Pitt, and never was a more triumphant reply than his answer to the arguments on the other side. Of the libel bill it is unnecessary to say a word. The country still profits by it, and regards it as a most important security to our constitutional freedom. By his exertions on the Russian armament, he had the satisfaction to save his country from at least one unnecessary, unjust, and expensive war. We must hasten to an occasion where his efforts were less successful.

The beginning of the French revolution gave universal satisfaction to the friends of liberty in this country. Soon after the taking of the Bastille, Mr Fox describes it "as the greatest, and much the best event that ever happened in the world;" and adds, "all my prepossessions against French connections for this country will be at an end, and indeed most part of my European system of politics will be altered, if this revolution has the consequence that I expect." When the king of France was brought back from Varennes, a report having been circulated in England that it was the intention of the national assembly to bring the queen to trial for her life, he composed a letter to Barnave, one of the leading members of the assembly, with whom he was personally unacquainted, exhorting him against such a measure of useless cruelty, which could not fail to bring disgrace on the cause of liberty. The letter was never sent, in consequence of the report proving to be unfounded; but we subjoin some extracts from it, in order to show the spirit in which it was written. After an apology for obtruding his advice on one who was unknown to him, except by reputation, and stating the bad impression that any unnecessary severity to the queen would produce in England; after praising the assembly for the firmness they had displayed on receiving the news of the king's escape, and urging them to show as much clemency and moderation in prosperity, as they had manifested coolness and resolution in danger; after stating the argument for sending the queen out of the country, or, at most, for confining her in a place of security, he proceeds as follows: "De l'autre coté, si on la juge cette malheureuse femme, qu'on la condamne, et qu'elle subisse son sort, je ne sais que trop bien que ce seraient les ennemis de la liberté qui en triompheront. On la peindra cette liberté comme feroce et cruelle, on tachera de la rendre odieuse, et parmi les âmes faibles on ne reussira peut-etre que trop bien. Le despotisme a toujours eu l'addresse de se servir des passions des hommes pour les subjuguer. Il a eu à ses gages la superstition et l'intérêt personnel, et il seroit bien facheux que la pitié, la plus aimable de toutes les faiblesses humaines, se rangeât aussi de son coté. Je ne sais si je me trompe, mais il me parait que vous êtes precisément dans la position où vous pouvez faire une action belle et genereuse sans le moindre danger; c'est-à-dire, que vous êtes dans la prosperité la moins equivoque. Vous avez donné par vos travaux la liberté à votre patrie, et vous trouvez dans elle une recompense aussi touchante que juste. Travaillez actuellement pour le genre humain, et faites aimer la liberté à toutes les nations de la terre, en prouvant qu'elle nourrit dans l'âme non seulement les vertus mâles comme le courage et la justice, mais aussi la douceur, la moderation, et la clemence." Such were the sentiments and conduct of a man, who was afterwards represented to his countrymen as the blind apologist of all the horrors of the revolution, and indifferent spectator of the calamities of the royal family of France.

As the revolution departed from its original character of justice and moderation, its favourers in this country began to fall off. Mr Burke, scandalized at the confiscation of church property, was the first of the Whig party to declare against it. His violent and outrageous quarrel with Mr Fox in the House of Commons is too well known to need to be here related. No event of his life had ever given such unfeigned sorrow to Mr Fox, as this breach with his old friend and political instructor. But he had soon many other losses of the same sort to deplore. The excesses of the revolution, the democratic form it assumed, the fear lest its example should prove contagious in England, filled with alarm the older, richer, and more aristocratic members of the Whig party. Younger and more ardent spirits, looking to the goodness of the cause, disregarded the unfitness of the instrument used to promote it; and, exulting in the progress of political freedom abroad, thought the occasion favourable for extending and enlarging our constitutional rights at home. A schism was gradually formed in the Whig party, which the formation of the Society of the Friends of the People, and the royal proclamation in May 1792, brought to a public explosion. Mr Fox was eagerly courted on both sides; but if he appeared to hesitate, it was only to keep his friends, if possible, together, and prevent a permanent separation, which he foresaw would invest the minister, as it did, with absolute power. But the revolution of the 10th of August, the massacres of September, the success of the French arms under Dumourier, the violence and indiscretion of the friends of reform at home, spread a panic terror over the land; and the minister who had trifled and temporised till it was too late, found himself unwillingly forced into a war, which he had not wisdom to avert or genius to conduct.

We cannot follow Mr Fox in his opposition to this disastrous war, nor in his subsequent efforts for the restoration of peace. On no occasion was the vigour of his intellect, the sagacity of his foresight, the firmness and resolution of his character, more conspicuous than during the struggle he maintained against overwhelming majorities from 1792 to 1797. Till the Duke of Portland, and other alarmists of the Whig party, joined administration in 1794, he always flattered himself with the hope of renewing his connection with his old friends, when their fears should have subsided; and at every harsh or violent act of the government his letters express surprise that the men with whom he had acted so long should support such measures. When finally separated from his old aristocratic connections, and convinced by fatal experience that the House of Commons had sunk into the passive instrument of ministerial power, his opinions became gradually more inclined to parliamentary reform, from utter despair of seeing the revival of those party connections to which he had been accustomed to look for the preservation of public liberty. But if he appealed to the constituent body against their representatives, he only followed the example which the court and his great opponent had given in the memorable dissolution of 1784. Nothing indisposed him so much against the House of Commons as the indifference it manifested on every occasion where liberty was infringed, or injustice committed by the government. "Arguments against the war and our alliances," he observes, in a letter written in 1794, "are favourably heard in the House of Commons, though they do not get us a vote; but sentiments of liberty, and complaints of oppression, are very little attended to, however well founded. In short, liberty is not popular; and of those who are attached to it there are too many who have wild and impracticable schemes of government, to which the miserable state we are in, both with respect to foreign affairs and our constitution, gives more plausibility and credit than they are by their own merit entitled to. The country seems divided (very unequally I admit) between the majority, who are subdued by fears or corrupted by hopes, and the minority, who are waiting sulkily for opportunities for violent remedies. The few who are neither subdued enough to be silent through fear, nor desperate enough to give up regular opposition, in expectation of more violent measures, are weak both in numbers and weight; but, though weak, we are right, and that must be our comfort." But, however changed the sentiments of the country, his own opinions of the value of political liberty were not altered. "I believe," says he, in another letter to the same correspondent, "the love of political liberty is *not* an error; but if it is one, I am sure I shall never be converted from it, and I hope you never will. If it be an illusion, it is one that has brought forth more of the best qualities and exertions of the human mind than all other causes put together; and it serves to give an interest in the affairs of the world, which without it would be insipid." "We live," he observes on another occasion, "in times of violence and of extremes; and all those who are for creating, or even for retaining, checks upon power, are considered as enemies to order. However, one must do one's duty, and one must endeavour to do it without passion." After relating the final junction of his old friends with administration, he adds, "You will easily imagine how much I feel the separation from persons with whom I had been so long in the habit of agreeing; it seemed in some way as if I had the world to begin anew; and, if I could have done it with honour, what I should best have liked would have been to retire from politics altogether; but this could not be done, and therefore there remains nothing but to get together what remains of our party, and begin, like Sisyphus, to roll up the stone again, which, long before it reaches the summit, may probably roll down again."

The last of these extracts shows that, notwithstanding the defection of some of the friends he most loved and esteemed, he was still convinced of the necessity of party connections, in order to maintain the cause of liberty in this country. He argues the question at length with his correspondent, and concludes by saying, "But the decisive argument upon the subject appears to me to be this: Is there any other mode or plan in this country by which a rational man can hope to stem the power and influence of the crown? I am sure that neither experience nor any well reasoned theory has ever shown any other. Is there any other plan which is likely to make so great a number of persons resist the temptations of titles and emoluments; and, if these things are so, ought we to abandon a system from which so much good has been derived, because some men have acted inconsistently; and because, from the circumstances of the moment, we are not likely to act with much effect?" It was with great reluctance, however, and with great violence to his own wishes, that he persevered in this fruitless struggle. "I am quite sick of politics," he says in August 1794, "and attend to them only because I think it a duty to do so, and that it would be unbecoming my character to quit them at such a moment." His desire to retire from public life became stronger in the following year. "I grow every day to think less of public affairs," he says in April 1795; "I wish I could be persuaded that it was right to quit public business, for I should like it to a degree that I cannot express; but I cannot yet think that it is not a duty to persevere. I am so sure that secession is the measure a shabby fellow would take in our circumstances, that I think it can scarcely be right for us; but, as far as wishes, no man ever wished any thing more. I am perfectly happy in the country. I have quite resources enough to employ my mind, and the great resource of literature I am fonder of every day. However, events and circumstances may happen which may make that right, which I am sure would be pleasant, and I think it not unlikely but they may."

The popular spirit manifested against the treason and sedition bills, in winter 1795, revived his public zeal, but was far from giving satisfaction to his mind. "My view of things," he writes in November 1795, "is, I own, very gloomy, and I am convinced that in a very few years this government will become completely absolute, or that confusion will arise of a nature almost as much to be deprecated as despotism itself. Ministers mean to bring on the first of these evils, and I cannot disguise from myself that there are but too many who wish for the second." After his success at the Westminster meeting against the bills, he says, "It is clear we have the popularity, and I suspect we shall have it universally among the lower classes. I need not tell you how I dislike this state of things, but I cannot submit quietly to Mr Hume's *euthanasia*, which is coming on very fast." As he became more persuaded of the existence of a strong spirit of liberty among the lower classes, he became more inclined to the popular doctrines of parliamentary reform. In 1796 he expresses himself in the following manner upon that subject: "Perhaps, instead of saying *now* that the power of the House of Commons ought to be first restored, and its constitution considered afterwards, it would be better to invert the order, and to say parliament should first be reformed, and then restored to its just influence. You will observe that I state this opinion as being mine *now*, in contradistinction to those times when the Whig party was only beaten, but not dispersed, and when I certainly *was* of a different opinion. At present I think we ought to go further towards agreeing with the democratic or popular party than at any former period, for the following reasons: *We*, as a party, I fear can do nothing, and the contest must be between the court and the democrats. These last, without our assistance, will either be too weak to resist the court, and then comes Mr Hume's *euthanasia*, which you and I think the worst of all events; or, if they are strong enough, being wholly unmixed with any aristocratic leven, and full of resentment against us for not joining them, will go probably to greater excesses, and bring on the only state of things which can make a man doubt whether the despotism of monarchy is not the worst of all evils."

The time at length arrived when the state of things to which he alluded in his letter of April 1795 came to pass. His remaining political friends were persuaded that it was useless to persevere longer in their parliamentary exertions, and that it was even "in some degree hurtful, as tending to deceive the country into an opinion that the House of Commons was still a place in which it was worth while to try the effect of argument and reason." When he found that no good was to be done in parliament, that no beneficial impression was to be made on the country, and that the friends for whom he was ready to sacrifice his time and inclinations wished him to retire from public life, with doubt and hesitation in his mind as to the propriety of the measure, he gave his consent to the secession; resolving no longer to attend his duty in the House of Commons, unless particularly called upon to do so by his own constituents.

Having once retired to St Anne's, he found such enjoyment in the calmness and tranquillity of a country life, that it was with the utmost difficulty he could now and then be brought back to the House of Commons. The happiest years of his life were those which he passed in retirement from 1797 to 1802. He still took a lively interest in public concerns, and applauded and encouraged the exertions of his friends when they returned to parliament, but he could seldom be induced to follow their example. His time passed placidly and agreeably in books, conversation, and the society of his family. He had always been fond of gardening, and his residence in the country gave him a turn for farming. Of the amusements of his early years the love of shooting was the only one in which he continued to indulge, and the exercise it gave him preserved his health. His passion for literature, which had never subsided entirely, revived and became stronger than ever. Poetry and criticism were his favourite pursuits, and history his amusement. He applied with ardour to the study of the Greek tragedians, and as his proficiency increased, he found an agreeable occupation for his mind in the niceties and difficulties of that noble language. Some time after his retreat he conceived the plan of writing a History of the Revolution of 1688. He had many years before expressed himself in the following manner, of the work of our great historian: "I think Mr Hume's History of Charles I. the most mischievous book that ever was written. It is written with infinitely more art than any other part of his work, and is, I think, in that view a masterpiece. I do not think any answer to it or comment on it would do much good, or at least not so much as another history of the times written with his art, or even with the half of it, in the opposite view." But, though his opinion of the utility of a new history of the civil war, as an antidote to Hume, may possibly have first turned his thoughts to a work on English history, the period he selected for his own labours shows that he had no intention to set himself up as a rival to that great historian. His sole object seems to have been, to tell the story of the Revolution, to explain how it was brought about, and to show in what its constitutional value consisted. Had he lived to complete his plan, the criticisms on Hume, in his introduction, would have formed but a small part of his book.

Mr Fox went abroad with Mrs Fox in summer 1802, partly from curiosity to see France after the extraordinary changes that had taken place in that country, and partly to collect documents for his history. As the constant friend of peace, he was received with enthusiasm wherever he went by the French people, and treated with distinguished civility and attention by their government. He had several long conversations with the first consul, in which the latter talked to him with the utmost freedom on a variety of topics; on the concordat then recently made, on the trial by jury, on the licentiousness of the English newspapers, on the difference between Asiatic and European society. On one occasion Napoleon having insinuated that Mr Windham was concerned in the assassination plots against his person, Mr Fox vindicated his old friend with warmth against so odious and unfounded an imputation. Having finished his labours at Paris, during which he collected a large mass of materials for his history, he went to La Grange, the country seat of his friend La Fayette, and after passing some days there most agreeably, returned to England.

On his arrival in London he found great irritation in England against the consular government, and an absurd cry for war raised by the newspapers, and re-echoed by all who expected in any way to profit by that calamity. Ministers were apparently undecided, and, in the hopes of confirming them in a pacific disposition, he resolved for a short time to renew his attendance in parliament. "I shall attend on the address," he says, "because, though, if the ministry is warlike, I have no hope of dissuading them; on the other hand, if they are pacific, I may serve in some degree to encourage them." Besides his general objections to war, where it could be avoided with honour, he thought there was "in this case a moral certainty of failing in our object, and of aggrandizing France still more than we had done." Peace should be preserved, "if it could be done with honour;" and he had no doubt it might, provided our government was so disposed. If Pitt, who had not yet declared himself, should be for peace and Addington, there would be no occasion for the old opposition taking an active part; but if he should join the war party, or "hold a conduct between peace and war," then Addington will want support, "and the support given him will be both useful and honourable." He had been told that he should "be as much abused for pacific language now as he had been ten years before, but being in parliament, he was determined not to blink such a question;" and, on making the trial, found "his speech in favour of peace better received by the house than any he had made since the Russian armament." The country in general, he was persuaded, was inclined to peace; and while there was "hope of contributing to prevent war, he felt himself in a manner bound" not to discontinue his attendance in the House of Commons. When the short session before Christmas closed, he still thought ministers sincerely desirous of maintaining peace. "If I have any fears," he says on the 29th of December 1802, "it is only from a suspicion of a want of courage in ministers to speak out what they really think, and if they should *long* continue to be afraid of speaking bold pacific language, ill humours may arise, and war begin without any wish for it in either government."

It has been invidiously said, that Mr Fox, after his return from Paris, was unwillingly dragged from his retirement by the importunity of his friends, in order to support their views in parliament, and that his health and comfort were sacrificed to their party objects. The fact is directly the reverse. It was he who urged them to attend, not they who solicited him. His return to public life was his own spontaneous act, unsolicited and unexpected by his friends. His object, in the first instance, was to assist in the preservation of peace; and when the message in March 1803 had opened his eyes to the real intentions of the ministry, his indignation at the hollowness and duplicity of their conduct made him persevere in his parliamentary attendance. From the state of parties in the House of Commons he began also to entertain hopes of the revival of a Whig opposition, such as had existed before the fatal schism in 1792; and with his opinions of the necessity of party connections, as the only means of maintaining public liberty in this country, there was no personal sacrifice he was not willing to make for the attainment of such an end. The revival of his former connection with his old friends was the object nearest to his heart; and in Lord Grenville, though a new associate, he found, as he had formerly done in Lord North, an honourable coadjutor, with whom he could act in perfect confidence, though they had differed warmly on points that were no longer the subjects of public discussion. He was even ready to form a junction with Mr Pitt, till he discovered that Pitt, though willing to join in opposing particular measures of administration, would not break with the court by going into regular opposition. It is a certain fact, that, of all his party, Mr Fox was the person most anxious to form a coalition with Lord Grenville; and that, whatever difficulties occurred to retard that junction, they arose not from him, but from his friends. He considered then, as he had done from the time of the American war, the influence of the crown to be the most dangerous enemy to good government in this country; and the violence expressed for war, after the royal message, contrasted with what he conceived to have been previously the general disposition for peace, he regarded as a strong confirmation of all his apprehensions. "The king's minister," he says in March 1803, "be he who he may, is in peace, at last, all powerful; whether or not, in case of a war, the universal apprehension of mischief from the weakness of those men could do any thing, may be more of a question, but even in that case I think the crown in earnest would beat us all." This influence, he contended, not only governed men's actions, but even swayed their opinions. "I should not be surprised," he says in January 1804, "if in a short time the present minister is reckoned the ablest man in the kingdom; or, if that cannot be compassed, it will be thought and maintained, that a minister without abilities is the best for this country." He was anxious for a junction of parties, not from motives of personal ambition, but in order to counteract this servility. "A stand should be attempted, which, though unsuccessful at present, will keep something alive against other times. To temporise is certain, absolutely certain, confirmation of the evil; no nation ever did, or ever can, recover from slavery by such methods."

The first distinct overture for a formal coalition of what were then called the new and old opposition, was made in January 1804, and came from the friends of Lord Grenville. It was proposed to co-operate in a systematic opposition, for the purpose of overturning Mr Addington's administration, and of substituting in its place one upon the most comprehensive basis possible. To this proposal Mr Fox was willing to have acceded at once; but, owing to some repugnance on the part of his friends, it was settled that the two parties should co-operate and concert together the measures to be brought forward in parliament, in order to give to their debates and divisions all the strength they could, without any formal or compact engagement in case of success. The same proposition had been made to Mr Pitt, who owned that the present ministry was weak and inadequate to the crisis, that their dismission would be a benefit to the country, and that, in case of such an event, an administration should be formed on the broadest possible basis. If his majesty, on such an occasion, were to send for him, he should think it right to endeavour to comprehend in the arrangement all parties, and even those who had been most hostile to him; but though, on many points, he would support the new opposition if it took place, he was determined never to engage with any set of men in systematic opposition. Such was the state of parties at the meeting of parliament in February 1804. As the session advanced Mr Pitt grew more hostile to ministers; and, after the Easter recess, the three parties in opposition acted in concert with so much vigour, that Mr Addington thought it prudent to resign. Mr Pitt, who was sent for to form a new administration, had previously declared that he would endeavour to form one in conjunction with Lord Grenville and Mr Fox; but if he found his majesty impracticable, he should feel himself bound to try one by himself. The result is well known. His majesty was found to be impracticable on the subject of Mr Fox. Lord Grenville, though unfettered by engagements, refused to concur in an administration from which Mr Fox was excluded; and, by his conduct on this occasion, "satisfied those" persons of the old opposition, "who had been most prejudiced" against a junction of the two parties. Mr Pitt, abandoned by all, except his personal friends and adherents, was compelled to coalesce with the wrecks of the administration he had contributed to destroy.

After various ineffectual attempts, during the recess, to strengthen the government, Mr Pitt found himself obliged, before the meeting of parliament, to take back Mr Addington into office. A fresh quarrel ensued; and, at the close of the session, Mr Addington (now Lord Sidmouth) and his friends again resigned. Insinuations were then thrown out of an intention to negotiate with opposition; but, if such overtures had been made, the new engagements contracted on the Continent, independent of other reasons, must have put a stop to the negotiation. Russia, offended at the arrogance of Napoleon, had expressed her desire to form a closer connection with Great Britain. It had been the advice of Mr Fox that advantage should be taken of this disposition to propose reasonable terms of peace to France, under the mediation of Alexander, and, if these were refused, to conclude a defensive alliance with Russia, but on no account to provoke a fresh Continental war, which must ruin Austria if unsuccessful. Unhappily this advice was not taken. Austria was seduced, or rather bribed, into a declaration of hostilities. The war was pre-eminently unfortunate, and all hope for a time extinguished of any balance to the power of France upon the Continent.

The death of Mr Pitt dissolved the administration he had formed. Lord Grenville was sent for by the king, and had no difficulty in persuading his majesty to accept of the advice and services of Mr Fox. When the different parts of the new administration were to be cast, his hope and desire of peace induced Mr Fox to take the office of secretary of state for foreign affairs; and, before his fatal illness, he had begun a negotiation for peace, with every apparent prospect of success. The short time he was in office prevented him from realizing the sanguine expectations which his friends and the public had conceived from his past conduct and principles of government. It ought to be remembered, however, that it was to his firmness Mr Windham was indebted for the success of his limited service bill; a measure that had to encounter every opposition which power and prejudice could raise against it; and that to his exertions, and to those of Lord Grenville, was owing a resolution of both houses of parliament to abolish the slave trade, which Mr Pitt, in the plenitude of his power, had failed to obtain.

Mr Fox had inherited an uncommonly vigorous constitution; but, about two years before his death, he had an illness at Cheltenham, which probably laid the foundation of the malady that occasioned his death. His attendance on Lord Nelson's funeral, in January 1806, brought on a complaint to which he was ever after occasionally liable. The duties of office, and the fatigue of constant attendance on the House of Commons, did not tend to restore or confirm his health. About the middle of June he had symptoms of dropsy, both general and local, and soon afterwards his complaint had made such alarming progress as to excite the greatest fears for his life. The universal interest excited in his fate afforded the surest evidence of his great popularity. From the remotest corners of the kingdom letters arrived daily to his family, expressing the deepest concern in his situation, and recommending remedies of all sorts for his disease. His malady, in the mean time, gained ground daily, and his physicians were at length compelled to have recourse to the common surgical operation for dropsy of the belly. The relief obtained, as usual, was but temporary. The operation was repeated, and soon after he fell into a state of languor, from which he never recovered He expired on the 13th of September 1806, having retained his senses and understanding to the last. It has been said that his death was accelerated by the exhibition of digitalis, administered in the vain hope of effecting a perfect cure of his disease; but the story is utterly false and unfounded, and has been publicly contradicted by his physicians. The cause of his complaint was ascertained to be a schirrous affection of the liver.

"Mr Fox," to use the words of one who knew him well during the last fifteen years of his life, and who has delineated his character with equal truth, force, and discrimination,[1] "united, in a most remarkable degree, the seemingly repugnant characters of the mildest of men and the most vehement of orators. In private life he was gentle, modest, placable, kind, of simple manners, and so averse from dogmatism, as to be not only unostentatious, but even something inactive in conversation. His superiority was never felt but in the instruction which he imparted, or in the attention which his generous preference usually directed to the more obscure members of the company. The simplicity of his manners was far from excluding that perfect urbanity and amenity which flowed still more from the mildness of his nature than from familiar intercourse with the most polished society of Europe. The pleasantry perhaps of no man of wit had so unlaboured an appearance. It seemed rather to escape from his mind than to be produced by it. He had lived on the most intimate terms with all his contemporaries distinguished by wit, politeness, or philosophy, or learning, or the talents of public life. In the course of thirty years he had known almost every man in Europe whose intercourse could strengthen, or enrich, or polish the mind. His own literature was various and elegant. In classical erudition, which by the custom of England is more peculiarly called learning, he was inferior to few professed scholars. Like all men of genius, he delighted to take refuge in poetry, from the vulgarity and irritation of business. His own verses were easy and pleasant, and might have claimed no low place among those which the French call *vers de société*. The poetical character of his mind was displayed by his extraordinary partiality for the poetry of the two most poetical nations, or at least languages, of the west, those of the Greeks and of the Italians. He disliked political conversation, and never willingly took any part in it."[2]

"To speak of him justly as an orator would require a long essay. Everywhere natural, he carried into public something of that simple and negligent exterior which belonged to him in private. When he began to speak, a common observer might have thought him awkward; and even a consummate judge could only have been struck with the exquisite justness of his ideas, and the transparent simplicity of his manners. But no sooner had he spoken for some time than he was changed into another being. He forgot himself and every thing around him. He thought only of his subject. His genius warmed and kindled as he went on. He darted fire into his audience. Torrents of impetuous and irresistible eloquence swept along their feelings and conviction. He certainly possessed above all moderns that union of reason, simplicity, and vehemence, which formed the prince of orators. He was the most Demosthenean speaker since the days of Demosthenes. 'I knew him,' says Mr Burke, in a pamphlet written after their unhappy difference, 'when he was nineteen; since which time he has risen, by slow degrees, to be the most brilliant and accomplished debater the world ever saw.'

"The quiet dignity of a mind roused only by great objects, the absence of petty bustle, the contempt of show, the abhorrence of intrigue, the plainness and downrightness, and the thorough good nature, which distinguished Mr Fox, seem to render him no unfit representative of the old English character, which, if it ever changed, we should be sanguine indeed to expect to see it succeeded by a better. The simplicity of his character inspired confidence, the ardour of his eloquence roused enthusiasm, and the gentleness of his manners invited friendship. 'I admired,' says Mr Gibbon, after describing a day passed with him at Lausanne, 'the powers of a superior man, as they are blended, in his attractive character, with all the softness and simplicity of a child; no human being was ever more free from any taint of malignity, vanity, or falsehood.'

"The measures which he supported or opposed may divide the opinion of posterity, as they have divided those of the present age. But he will most certainly command the unanimous reverence of future generations, by his pure sentiments towards the commonwealth; by his zeal for the civil and religious rights of all men; by his liberal principles, favourable to mild government, to the unfettered exercise of the human faculties, and the progressive civilization of mankind; by his ardent love for a country of which the well-being and greatness were, indeed, inseparable from his own glory; and by his profound reverence for that free constitution which he was universally admitted to understand better than any other man of his age, both in an exactly legal and in a comprehensively philosophical sense." (Q. Q. Q.)

FRACASTOR, JEROME, one of the most learned men of his time, was born at Verona in the year 1483. Two singular circumstances are related of him in his infancy; one that his lips adhered so closely when he came into the world, that a surgeon was obliged to divide them with his incision knife; and the other, that his mother was killed with lightning, whilst he, though in her arms at the moment, escaped unhurt. Fracastor was a man of such admirable parts, and made so great progress in every thing he undertook, that in time he became eminently skilled not only in the belles lettres, but in most arts and sciences.

---

[1] *Character of Mr Fox*, by Sir James Mackintosh. Published in Dr Parr's Collection, entitled *Characters of Mr Fox*, by PHILOPATRIS VARVICENCIS.

[2] This is true of Mr Fox in the latter part of his life only. Till his separation from his old friends in 1793 his mind was too full of political subjects not to take an eager part in political conversation even in private; and, when a young man, instead of being somewhat inactive in conversation, he was very much the reverse. Dr Johnson was mistaken in supposing him habitually silent when in company, and has assigned a reason for his supposed taciturnity quite inconsistent with his real character.

He was a poet, a philosopher, a physician, an astronomer, and a mathematician; and he was also a man of consequence in his time, as appears from the fact of Paul III. having made use of his authority to remove the council of Trent to Bologna, under the pretext of a contagious distemper, which, as Fracastor declared, made it no longer safe to continue at Trent. He was intimately acquainted with Cardinal Bembo, Julius Scaliger, and most of the great men of his time. Fracastor died of apoplexy at Casi, near Verona, on the 8th of August 1553; and in 1559 the town of Verona erected a statue in honour of him. Fracastor was the author of many works, both as a poet and a physician; but never man was more disinterested in both capacities, for as a physician he practised without fees, and as a poet he was indifferent to fame, after which the tuneful tribe in general so ardently aspire. It is owing to this that we have so little of his poetry in comparison of what he wrote; and that, not to mention other compositions, his odes and epigrams, which were read in manuscript with infinite admiration, have now been lost. His medical productions are as follow: 1. *Syphilidis, sive Morbi Gallici libri tres*, Verona, 1530, in 4to, afterwards frequently reprinted; 2. *De Vini Temperatura*, Venice, 1534, in 4to; 3. *Homocentricorum, sive de Stellis liber unus*, and *De Causis Criticorum Dierum libellus*, Venice, 1535, in 4to; 4. *De Sympathia et Antipathia Rerum liber unus; De Contagionibus et contagiosis Morbis, et eorum curatione, libri tres*, Venice, 1546, in 4to. All the poetical productions of Fracastor were collected and printed at Padua, 1728, 8vo. His complete works appeared for the first time under the title of *Hieronymi Frascatorii Veronensis Opera Omnia, in unum proxime post illius mortem collecta; accesserunt Andreæ Naugerii patricii Veneti Orationes duæ, Carminaque nonnulla.* Venetiis apud Juntas, 1555, in 4to. Besides the works already mentioned, there are included in this collection the three following, which appeared for the first time, viz.: 1. *Naugerius, sive de Poetica dialogus; Turrius, sive de Intellectione dialogus, libri* ii.; 2. *Alcon, sive de cura Canum Venaticorum*; 3. *Frascatorius, sive de Anima dialogus.*

FRACHES, in the glass trade, are the flat iron pans into which the glass vessels already formed are put when in the tower over the working furnace, and by means of which they are drawn out through the leers, that they may be taken gradually from the fire, and cool by degrees.

FRACTION, in *Arithmetic* and *Algebra*, a part or division of an unit or integer; or a number which stands to an unit in the relation of a part to its whole. The word literally imports a broken number.

Fractions are usually divided into decimal, sexagesimal, and vulgar. See ALGEBRA and ARITHMETIC.

FRACTURE, in *Surgery*, a rupture of a bone, or a solution of continuity in a bone, when it is crushed or broken by some external cause. See SURGERY.

FRAME, in *Joinery*, a kind of case, in which a thing is set or enclosed, or even supported; as a window frame, a picture frame, and the like.

FRAME, among printers, is the stand which supports the cases.

FRAME, among founders, is a kind of ledge enclosing a board, which, being filled with wetted sand, serves as a mould to cast their works in.

FRAME is more particularly used for a sort of loom, on which artificers stretch their linens, silks, or stuffs, to be embroidered, quilted, or the like.

FRAME, among painters, is a kind of square, consisting of four long slips of wood joined together, whilst the intermediate space is divided by threads into several little squares like a net, and hence sometimes called *reticula.* It serves to reduce figures from great to small, or to augment their size from small to great.

FRAMLINGHAM, a market-town of the county of Suffolk, of the hundred of Loes, eighty-eight miles from London. It is an ancient but well-built town, situated on an elevated spot, near to which is the source of the river Ore. There are ruins of an ancient castle, supposed to have been built by the Saxons, the walls of which are forty-four feet in height, and eight in thickness. This castle was the residence of Queen Mary in 1553. The church is a handsome building, constructed of black flints. The market-place is large, and on Saturday well supplied. The population amounted in 1801 to 1854, in 1811 to 1854, in 1821 to 2327, and in 1831 to 2445.

FRAMMERSBACH, a bailiwick of the circle of the Lower Maine, in the kingdom of Bavaria, extending over seventy square miles. It contains one city, thirty villages, and 764 scattered single houses, with 4650 inhabitants. The city of the same name is situated on the Lahn, and contains 452 houses, and 2460 inhabitants.

FRAMPTON ON SEVERN, a town of Gloucestershire, in the hundred of Whitstone, 108 miles from London. There is here a considerable manufactory of iron and of wire. At high tides the river Severn occasionally floods a large part of the parish. The population amounted in 1801 to 860, in 1811 to 864, in 1821 to 996, and in 1831 to 1055.

FRANCAVILLA, a city of the province of Otranto, in the kingdom of Naples. It is situated in the centre of the province, and surrounded with several small lakes. It contains 11,108 inhabitants, who grow much cotton, and make it into various kinds of goods. It also produces good wine, and has considerable internal trade.
